ABSTRACT

To better understand our ocean would be to better describe one of the largest ecosystems on planet Earth, better quantify the geochemical processes that control Earth's climate, and better regulate natural resources stored in it's depths. *Expeditionary science* is the art of collecting *in situ* observations in a target environment so as to build approximate models of underlying environmental properties that move us towards better understanding. By the nature of ocean research, robotic platforms are a dominant technology driving *in situ* observations for expeditionary science in the deep sea. Historically, depth-capable autonomous underwater vehicles (AUVs) have been used to perform simple surveying tasks in the deep ocean (e.g., bathymetric mapping) that can be fully pre-specified by human operators and which yield high-quality reconstructions of static fields. However, there is urgency to utilize these platforms to generate rich data products of spatiotemporal distributions, such as chemical plumes. To treat spatiotemporal distributions as static distributions for sample collection with the oceanic science fleet requires access to a dynamics model of the environment, over which trajectories can be optimally placed for a given task. In general, perfect knowledge of the underlying distribution of a target environment is unattainable, and so must be inferred from observations. As most *in situ* scientific instruments yield point-measurements, considerable uncertainty is placed over the form of the dynamics due to extreme partial observability. In this thesis, planning under uncertainty for robotic expeditionary science is addressed by embedding scientific knowledge as a strong inductive prior for tractable model learning. Applied specifically to the problem of charting the spatiotemporal structure of deep-sea hydrothermal plumes, algorithmic contributions are presented which show how to *perceive* plumes, *predict* their state far into the future (e.g., multiple days), and *plan* informative fixed trajectories. Each chapter will discuss the technical and scientific implications of embedding scientific knowledge into algorithmic representations, grounding the discussion with results from field trials completed in November 2021 with AUV *Sentry* at the Guaymas Basin, Gulf of California.

1 INTRODUCTION

It is a wholesome and necessary thing for us
to turn again to the earth and in the contem-
plation of her beauties to know the sense of
wonder and humility.

Rachel Carson

Life on Earth is inextricably entwined with its environment, and understanding the environment has been a human endeavor throughout history. The environmental sciences are the multidisciplinary, academic disciplines which aim to understand the Earth, its ecosystems, and its processes. Today with the aid of technology, environmental discovery has extended from the deepest trenches in the ocean to the uppermost atmosphere, and there is growing awareness of the complexity of life-sustaining processes which underlie the surface beauty.

Just as in the past so is true today, *in situ* observational studies, or *expeditions*, serve as the foundation on which scientific discovery and model development are predicated in the environmental sciences. Traveling to and being present in an environment in order to collect physical samples or record first-hand observations is the gold standard by which studies are held. The development of remote observational technologies (e.g., imaging satellites) has revolutionized the ability to collect e.g., global-scale datasets of climate, but has yet to have the spatial or temporal resolution to better *in situ* analysis

of many terrestrial systems¹, and they fully fail to resolve underwater or subterranean domains.

Robots are uniquely well-positioned to advance long-term monitoring of and exploration in meso-scale² planetary environments through autonomous expeditions. By virtue of their form, robots can be used in extreme places (e.g., deep sea), dangerous scenarios (e.g., edge of calving ice sheets), or long-term missions (e.g., Mars exploration). Increasingly, robotic platforms are being developed for scientific expeditions, but their autonomous capabilities are typically limited to executing predetermined hand-designed trajectories, e.g., uniform coverage lawnmowers.³ This restriction is often applied in order for trajectories to be rigorously checked by teams of science or engineering staff prior to execution as a policy of risk reduction, and for ease of supervision during execution. Operating without agency (i.e., nonadaptively) necessarily restricts the class of phenomena that can be effectively studied by expeditionary scientific robots. For instance, spatiotemporal distributions—deep sea hydrothermal plumes, algal blooms, weather cells—can be severely under-sampled or missed using nonadaptive strategies.⁴ Given the ubiquity of spatiotemporal phenomena and the cost of scientific field operations, it is critical to improve the efficacy of robots as autonomous scientific tools and extend their capabilities.

In this thesis, the challenges of performing informative sampling trajectories with expeditionary robots in spatiotemporal environments will be closely studied. This research spans theoretical to practical challenges and considerations, and was performed in close collaboration with scientists and engineers in fields including oceanography and geochemistry, computational statistics, robotics, and data science. Chief among the challenges addressed in this research is the problem of uncovering the underlying

¹Indeed, many remote instruments require *in situ* observations for calibration anyway.

²tens of meters to several kilometers

³Camilli *et al.*, “Tracking hydrocarbon plume transport and biodegradation at Deepwater Horizon”.

dynamics of a spatiotemporal distribution in a target environment. With access to a perfect physics model of an environment, trajectories for a robotic platform could be exactly produced for some sampling task. However, rarely (and arguably never) is such a perfect model of an environment available. Instead, there is considerable *uncertainty* about the underlying form of the dynamics model⁵ To reduce uncertainty, roboticists and scientists both typically turn to data; here in the form of *in situ* observations. Unfortunately, data that can be collected in real field trials with mobile platforms tends to be noisy and extremely partially observable—that is, the observations are only at point locations in time and space, and may be indirect measurements of a desired field of interest. Practically, data-driven models trained with this type of data would require a huge number of samples in order to generalize a useful simulator for planning; a luxury that, in the field, is typically not afforded due to limited opportunities for deployments and finite mission timelines.

The problem of discovering a useful forward simulator for a target environment is not impossible, however. Decades of research have been dedicated to the recovery of environmental models by experimental trials and mathematical reasoning via scientists. For instance, the Navier-Stokes equations, which describe the motion of viscous fluids, are the philosophical, mathematical, and experimental results of Leonhard Euler, Claude-Louis Navier, and George Gabriel Stokes stretching from 1757 to 1850. In this case, each mathematician started from the knowledge of their predecessor(s), and extended the sophistication of the model in turn. This is a natural scientific process, and it is a process that is well suited for algorithmic adaptation. The emergence of the field of scientific machine learning is some evidence, as neural networks,⁶ Gaussian Processes

⁵Both epistemic and aleatoric. Aleatoric uncertainty in this case comes from the chaotic nature of spatiotemporal distributions (for instance, turbulent flows). Epistemic uncertainty is definitional, as we have uncertainty of the model.

⁶Mohan *et al.*, “Compressed convolutional LSTM: An efficient deep learning framework to model high fidelity 3D turbulence”; Raissi *et al.*, “Physics-informed neural networks: A deep learning framework for solving forward and inverse problems involving nonlinear partial differential equations”;

(GPs),⁷ and similar representations⁸ are developed which often leverage numerical scientific models or physical principles to approximately find novel forward simulators from relatively limited trajectory data in space-time.

To extend this algorithmic theory to field settings in which computational time is typically severely limited and field observations are corrupted via noise, the foundational⁹ principles of an assumed underlying dynamical model may still be an informative basis on which to learn. For instance, the concepts of non-divergence in flow fields and conservation of mass, and simplified models of time-averaged behaviors, can serve as an inductive bias¹⁰ for probabilistic data-driven models. Using *physically-informed structure* reduces the burden on the data alone for recovery of a dynamics model and the use of idealized analytical models can be considered a principled technique for identifying a reduced-basis for inference (rather than finding a latent space via the data directly). As some in robotics may say, however, there is no free lunch. The use of physically-informed structure trades sample efficiency for increased computational cost at deployment time (in comparison to purely data-driven techniques). However, this trade-off can be tuned for the underlying models available, the sampling task at hand, and the operational logistics during field opportunities.

In a field setting, embedding scientific knowledge into probabilistic models for robot learning requires additional, necessary algorithmic infrastructure. In particular, the

⁷Raiissi *et al.*, “[Numerical Gaussian processes for time-dependent and nonlinear partial differential equations](#)”.

⁸Brunton *et al.*, “[Discovering governing equations from data by sparse identification of nonlinear dynamical systems](#)”; Kulkarni & Lermusiaux, “[Advection without compounding errors through flow map composition](#)”.

⁹and implicitly more straightforward or simpler to compute

¹⁰The term *inductive bias* has a mixed connotation in learning. Designing an inductive bias will, definitionally, bias a learner towards the assumptions for unseen data. This is wonderful for an environmental context in which we’re guaranteed to seeing things that were not in the original training data and for which grounded principles imply underlying structure, but in other contexts (particularly social and cultural), inductive bias in learned models may reflect and enforce systemically inappropriate or unconscious assumptions.

observations that a robot collects must correspond to the internal representation used by the robot (it's belief) with the science models embedded. As scientific observations are typically taken by heterogeneous sensors with different operating principles¹¹, the choice of observation model is not straightforward. Indeed, modern scientific research rests on the interpretation *in situ* observations. While it is unreasonable to assume that a roboticist become a domain expert in a particular scientific field in order to plan useful trajectories¹², familiarity with the forms, limitations, and working principles of critical science sensing infrastructure is necessary in order to make advances in modeling and planning. This further implies that the development of expeditionary robotics cannot happen in a vacuum; collaboration with scientists who will ultimately use this technology must be undertaken.

Finally, the planning architecture that utilizes a physically-informed model must be considered. Planning trajectories for expeditionary robots must work under practical, operational constraints that can disrupt or inhibit the planning process. In the case that multi-hour missions need to be completely pre-specified and safety-checked by dedicated engineers, it is not unreasonable to need a plan computed hours in advance of a launch window. If this launch window moves in the case of weather delays, for instance, just carrying out the plan as designed could lead to poor performance in sampling spatiotemporal distributions, as the plan was generated over forecasts timed for the original launch window. To account for this inevitability¹³ the plan that is designed must either be temporally invariant (which is algorithmically difficult to achieve), or easily modified, potentially by hand, to account for the changing conditions and avoiding a multi-hour long replanning-rechecking procedure. Easy modification can only be done if the model, and the resulting trajectory designed with this model, are fully

¹¹And therefore may measure different phenomenon which may have complicated interrelationships.

¹²This is not to suggest that scientists could not become autonomy designers in the future of expeditionary robotics, however.

¹³inevitable, in that the unexpected is expected when in the field.

interpretable and the trajectory can be truncated or extended to meet changing timing demands.

This thesis presents the case for embedding scientific knowledge into the observation (*perception*), belief (*prediction*), and decision-making (*planning*) frameworks of an autonomy system to tackle core challenges related to vehicle non-adaptivity, partial observability in spatiotemporal domains, and operational restrictions. To ground the work, the specific expeditionary problem of deep-sea hydrothermal plume charting is closely analyzed, and a field deployment with autonomous underwater vehicle (AUV) *Sentry* in the Guyamas Basin, Gulf of California is used to demonstrate the algorithmic contributions to be presented. Deep-sea hydrothermalism is the thermal and geochemical circulation of seawater driven by magmatic activity. Characterizing interaction between the magmatic layer, basaltic crust, and deep ocean biosphere is of contemporary interest with this thesis, as concerted interest in deep sea mining (for recovery of rare earth materials and metals) and deep carbon sequestration are hotly developing fields. Hydrothermalism plays a critical role in these processes, as a nutrient (and metals) pump, indicator for geological activity, and sustainer of unique ecosystems. To chart hydrothermal plumes means to survey the structure of the warm, nutrient-rich water that is ejected from vents on the seafloor. As plumes are subject to instantaneous turbulence, advective crossflows, and complex mixing, predicting the location of a plume from point observations poses a considerable challenge for planning trajectories for a nonadaptive robotic platform.

CLOSING PARAGRAPH

1.1 HYDROTHERMALISM IN THE DEEP OCEAN

Hydrothermal vents in the ocean were first observed in 1977 at the Galapagos Rift,¹⁴ and since have been discovered around the world and the subject of considerable geo-dynamical and biogeochemical study. Seafloor venting sites, energized by magmatic sources, release fluids between 20-400 °C (background deep ocean temperatures are approximately 2 °C) and imbued with minerals, metals, dissolved gases, and other compounds.¹⁵ These warm, nutrient-pumping sites in the deep ocean have created oases for unique micro- and macro-fauna,¹⁶ and the venting fluids, called plumes, can deposit minerals and metals over kilometer scales CITE. Detection and characterization of seafloor hydrothermal venting are critical for understanding fundamental interactions between the deep ocean, its underlying basaltic crust, the deep biosphere, and (bio)geochemical fluxes.

Contemporary to the writing of this thesis, increased political and economic interests in mining seafloor resources, and environmental interests in sequestering reclaimed carbon in the deep ocean, have put a cultural spotlight on hydrothermalism and the oceanic crust. Questions related to mineral and metal deposition from plumes highlight the acute scientific need to better study not just hydrothermal vents themselves, but the plume structures that are produced by them which are the primary drivers of nutrient injection in the deep ocean biosphere. Scientific studies that benefit from directly charting the spatiotemporal structure of a plume include those which characterize the transport and deposition of particulates, the distribution and transport of biological materials (including microbes) in the deep ocean, and field-based statistical modeling of turbulent water mass mixing.

¹⁵Jannasch & Mottl, “Geomicrobiology of deep-sea hydrothermal vents”; Martin *et al.*, “Hydrothermal vents and the origin of life”.

¹⁶Corliss *et al.*, “Submarine thermal springs on the Galapagos Rift”.

Arguably beginning with the Morton, Taylor, and Turner (MTT) model for buoyant plumes derived in the 1950s,¹⁷ and the re-derivation specifically for hydrothermal plumes in the late 1980s by Speer and Rona,¹⁸ our understanding of hydrothermal plumes is largely based on laboratory experiments and sparse, corroborating field measurements. These idealized models describe a roughly two part plume structure composed of a buoyant stem and a neutrally-buoyant layer. The buoyant stem is a spatially small expression that describes the fluid that rapidly rises from an originating vent orifice, largely driven by buoyant forces that result in the different in density between the warm ventint fluid and the ambient seawater. The neutrally-buoyant (or equivalently non-buoyant) layer describes the spatially large spread of vent-derived fluids along the isopycnal of equal density with the ambient seawater¹⁹. In subsequent studies, state-of-the-art hydrothermal plume models incorporate time-varying Navier-Stokes models and more complicated fluid structures²⁰. Mathematically, these models describe what has been practically well-understood in observational studies: the spatiotemporal distribution of plumes is instantaneously complicated and on small scales (meters, minutes) driven by compounding, chaotic factors that are difficult to calibrate.

FIGURE HERE??? – Plume description; images

The complication of finely modeling hydrothermal plumes puts a fine point on the challenge of placing scientific instruments at the right place at the right time to gather an informative measurement for a scientific task. To chart hydrothermal plumes requires grappling with uncertainty over the underlying dynamics of a target environment due to the extreme partial observability of point *in situ* measurements in a continuous three-

¹⁷Morton *et al.*, “Turbulent gravitational convection from maintained and instantaneous sources”.

¹⁹Readers are referred to (Yoerger *et al.*, “Autonomous and remotely operated vehicle technology for hydrothermal vent discovery, exploration, and sampling”) for an illustrative description and figure.

²⁰e.g., (Lavelle *et al.*, “A turbulent convection model with an observational context for a deep-sea hydrothermal plume in a time-variable cross flow”; Xu & DiIorio, “Deep sea hydrothermal plumes and their interaction with oscillatory flows”)

dimensional volume over time influenced by complicated spatiotemporal dynamics of water mixing, tidal advection, and chaotic turbulence. The notion of uncertainty has implications for solving both the *inverse* and *forward* problem inherently posed in hydrothermal plume charting. Discovering the underlying model from a set of data, the inverse problem, is known to be ill-posed in spatiotemporal systems CITE, suggesting that the information content of every sample has an outsized effect on the accuracy of recovered dynamics. With a known dynamics model, forward simulating a model with uncertainty placed over initial conditions or descriptive parameters requires propagating that uncertainty forward. In time-dependent models, even modest amounts of uncertainty can accumulate quickly over short horizons CITE, yielding essentially uninformative predictive state estimates for planning. A principled treatment of uncertainty, particularly the identification of *useful* uncertainty for planning, is necessary.

WORDS ON HOW PEOPLE HAVE THOUGHT ABOUT UNCERTAINTY IN HYDROTHERMAL SYSTEMS

1.2 INFORMATIVE PATH PLANNING IN THE FIELD

Oceanographic research expeditions are an undertaking that requires the coordination and collaboration of a science party, external engineering teams that maintain and operate the scientific equipment used during studies, and the captain and crew aboard a research vessel (on which everyone lives and works during operations). Deep-sea (depths below the mesopelagic zone starting at 1000 m) capable robotic platforms used in oceanic research are assets independently maintained from a ship, and typically requested on a per-expedition basis. AUV *Sentry* may be deployed on tens of expeditions in a given year, with up to 250 days at sea. Safety of both people and equipment are held to the highest importance. Further, the critical role of *Sentry* in oceanographic re-

search drives the strict operational policies that dictate *Sentry* deployments to prevent vehicle loss or damage.

It is with this context that *Sentry* deployments are designed by the science party and ultimately approved by the *Sentry* engineering team. In a typical workflow, the science party may provide a set of coordinates or waypoints they generate based on bathymetric maps, prior knowledge, or previous data (when available). The *Sentry* team design survey trajectories based on these coordinates and respecting basic operational constraints of the vehicle (e.g., speed, minimum/maximum altitude from the seafloor). With approval of the *Sentry* team, science party, and captain, the survey is then executed. A single “dive” of *Sentry* is multiple hours (typically not less than 5 hours, and under 24 hours). At the conclusion of a dive, *Sentry* is recovered from the ocean and data products containing hundreds of thousands of point measurements from multiple heterogeneous sensors are made available to the science team within a few hours after *Sentry* returns to the deck. Depending on the length of the dive, 12-18 hours of vehicle cycling time (e.g., recharging, instrument maintenance, preparation for the next deployment) are required. Based on the length of a particular expedition and other ongoing research activities, *Sentry* may be deployed only a handful of times.

The complexity of these basic operations for *Sentry* alone, in addition to the burden of coordinating several other ongoing scientific projects happening simultaneously, day-to-day operational changes, and unforeseen discoveries and hurdles make performing “closed loop science” with robot platforms a challenge while at sea. For hydrothermal plume monitoring, a combination of sensor streams need to be used to make confident plume detections,²¹ but information about exact tidal state, state of the venting source, and background sea characteristics are typically not available in these products, and can require fusing data products from other instruments deployed on a cruise, if available.

²¹Jakuba, “Stochastic mapping for chemical plume source localization with application to autonomous hydrothermal vent discovery”.

The planning challenge is further exacerbated when the design of a new mission requires not just deep analysis of the collected data, but forecasting the implications of those data onto a new day, new site, or new objective.

1.2.1 PERCEIVING

Discovering hydrothermalism, classifying examples, processing sensors, not having access to ground truth.

1.2.2 PREDICTING

1.2.3 PLANNING

Overcoming operational challenges and working within the framework of logistics at sea. Enabling decision-making not just by autonomous agents, but also by scientists/engineers.

1.3 THESIS OVERVIEW

The contributions of this thesis are...

The remainder of this thesis is organized as follows...

2 PROBLEM SETTING

To collect useful samples of a spatiotemporal field using a robotic platform is to pose a *sequential decision-making* problem. In this setting, we assume that the measurements that can be collected are partial observations of the unknown spatiotemporal environment, and the actions the robot can take in sequence are operationally constrained. We can formally state this problem as a partially observable Markov decision process (POMDP). Let $\Pi(\cdot)$ denote the space of probability distributions over the argument. A finite horizon POMDP can be represented as tuple: $(\mathcal{S}, \mathcal{A}, T, R, \mathcal{Z}, O, b_0, H, \gamma)$, where \mathcal{S} are the states, \mathcal{A} are the actions, and \mathcal{Z} are the observations. At planning iteration t , the agent selects an action $a \in \mathcal{A}$ and the transition function $T : \mathcal{S} \times \mathcal{A} \rightarrow \Pi(\mathcal{S})$ defines the probability of transitioning between states in the world, given the current state s and control action a . The transition function governs both how the state of the robot will evolve, given a chosen action, and the potentially stochastic evolution of the underlying spatiotemporal environment. After the state transition, the agent receives an observation according to the observation function $O : \mathcal{S} \times \mathcal{A} \rightarrow \Pi(\mathcal{Z})$, which defines the probability of receiving an observation, given the current state s and previous control action a . The reward function $R : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$ serves as a specification of the task, assigning the states of the world that are useful for a given scientific objective high reward and others low reward. A POMDP is initialized with belief $b_0 \in \Pi(\mathcal{S})$ — an initial probability distribution over state — and plans over horizon $H \in \mathbb{Z}^+$ with discount factor $\gamma \in [0, 1]$.

As the robot moves through the world, it selects actions and receives observations. Since the state of the world is not directly observable in a POMDP, the robot maintains a probability distribution over possible states (i.e., belief) and must update this distribution each time it takes an action and receives an observation. Given the transition and observation models, the belief can be updated directly using Bayes rule using a Bayes filter Särkkä, [“Bayesian filtering and smoothing”](#):

$$\tau(b_{t-1}, a_{t-1}, z_t) = b_t \triangleq \Pi(S_t | a_0, z_0, \dots, a_{t-1}, z_{t-1}, z_t) \quad (2.1)$$

$$= \Pi(S_t | b_{t-1}, a_{t-1}, z_t) \quad (2.2)$$

$$= \frac{\int_{s \in \mathcal{S}} O(s, a_{t-1}, z_t) T(s, a_{t-1}, s') b_{t-1}(s')}{\Pi(z_t | b_{t-1}, a_{t-1})} \quad (2.3)$$

where $\tau(b, a, z)$ is the updated belief after taking control action a and receiving observation z (Eq. (2.3)). Unfortunately, Eq. (2.3) is intractable to compute directly and an approximate Bayesian inference procedure is required to represent the belief (e.g., Kalman filter Welch, Bishop, *et al.*, [“An introduction to the Kalman filter”](#), particle filter Silver & Veness, [“Monte-Carlo planning in large POMDPs”](#), or variational methods).

Due to the stochastic, partially observable nature of current and future states, the realized reward in a POMDP is a random variable. Optimal planning is defined as finding a horizon-dependent policy $\{\pi_t^* : \Pi(\mathcal{S}) \rightarrow \mathcal{A}\}_{t=0}^{H-1}$ that maximizes expected reward: $\mathbb{E}\left[\sum_{t=0}^{H-1} \gamma^t R(S_t, \pi_t(b_t)) | b_0\right]$, where b_t is the updated belief at time t , conditioned on the history of actions and observations. The recursively defined horizon- h optimal value function V_h^* quantifies, for any belief b , the expected cumulative reward of following an

optimal policy over the remaining planning iterations: $V_0^*(b) = \max_{a \in \mathcal{A}} \mathbb{E}_{s \sim b}[R(s, a)]$ and

$$V_h^*(b) = \max_{a \in \mathcal{A}} \mathbb{E}_{s \sim b}[R(s, a)] + \gamma \int_{z \in \mathcal{Z}} \Pi(z \mid b, a) V_{h-1}^*(\tau(b, a, z)) dz \quad h \in [1, H-1], \quad (2.4)$$

The optimal policy at horizon h is to act greedily according to a one-step look ahead of the horizon- h value function. However, Eq. (2.4) is intractable for large or continuous state, action, or observation spaces and thus the optimal policy must be approximated. Much of the art of practical decision-making uncertainty is making well-designed algorithmic and heuristic choices that enable efficient and robust planning algorithms.

5 DISCOVERING HYDROTHERMALISM FROM AFAR

To track a spatiotemporal phenomenon requires first being able to sense it. There are two core challenges associated with perceiving hydrothermal plumes: existence (and availability) of technology and interpretation of heterogeneous data streams. With respect to deep-sea capable instrumentation, temperature, pressure, conductivity, and turbidity are all examples of quantities that can be near instantaneously measured by existing state-of-the-art *in situ* sensors. However, for many geochemical quantities such as dissolved greenhouse gases (e.g., carbon dioxide, methane), few (if any) commercial sensors with rapid response times suitable for use on a mobile platform exist. This limitation has had severe impact on the ability for scientists to study phenomena like hydrothermal plumes, as these entities may be difficult to identify only from temperature or conductivity anomalies, but are expected to be significantly geochemically distinctive from background seawater levels of the ocean.¹ In this chapter, two experimental dissolved methane instruments are used in an ocean trial at a hydrothermal basin. The utility of methane as a signal for the presence of plume waters is compared against other standard oceanographic equipment.

¹Jakuba, “Stochastic mapping for chemical plume source localization with application to autonomous hydrothermal vent discovery”; Scholz *et al.*, “Shelf-to-basin iron shuttle in the Guaymas Basin, Gulf of California”.

The second challenge, interpreting heterogeneous data streams, is a problem that arises when the quantity of interest is a conceptual entity, rather than an absolute one. Concretely; temperature can be directly observed with a single instrument, but “plumes” cannot be directly sensed as they are definitionally an aggregation of properties distinct from background seawater. So, to observe “plumes” requires interpreting data from multiple heterogeneous sensors in order to identify which robot locations observed plume-derived fluids, and which did not. Heterogeneity in this case refers to the different operating principles and observable quantities that are measured by a suite of scientific sensors. As these sensors may respond to the environment at different time scales, have different sensitivities, and measure quantities which may physically manifest themselves differently in unique spatiotemporal regions of a plume (and may be unique to each plume that is surveyed), it is not straightforward to universally filter these data streams for plume detections. To this end, this chapter presents several methods for detecting “change-points” in data streams that can be used to indicate anomalous features in a datastream unique to hydrothermalism, and which can be broadly applied to many different types of field settings.

The content that proceeds from this point is directly adapted from Preston *et al.*, “[Discovering Hydrothermalism from Afar: In Situ Methane Instrumentation and Change-Point Detection for Decision-Making](#)”. The supplemental information for this publication is also reproduced as Appendix A in this thesis.

5.1 INTRODUCTION

Detecting and characterizing seafloor hydrothermal vents is critical in understanding the fundamental interactions among the geochemical and biological processes on the seafloor, and the fluxes that these processes cause to and from the deep ocean. Since the

first discovery of deep sea hydrothermalism in 1977,² hundreds of hydrothermal venting sites have been discovered and analyzed.³ These studies reveal that hydrothermal vents play a major role in ocean-scale elemental and micronutrient budgets,⁴ serve as nutrient pumps to the deep ocean,⁵ and sustain abundant and unique (e.g., chemosynthetic) forms of complex life.⁶ Hundreds of vent sites are hypothesized to exist and yet remain undiscovered in the deep ocean,⁷ limiting efforts to constrain nutrient and energy budgets of the deep ocean, to assess the magmatic budget hypothesis which estimates the global stock of hydrothermal activity, and to understand these novel ecosystems.

Exhaustive search of the seafloor is an impractical method for discovering new vents due to the scale of the ocean environment. Instead, adaptive surveying strategies and novel sensing technologies can be combined to detect hydrothermalism far (over 1 km laterally) from the plume source using water column observations. Hydrothermal plumes form due to a density difference between background seawater and (often significantly) heated vent fluids. The resulting buoyant force creates a coherent rising stem from the vent (the buoyant stem) and a spreading cloud (the neutrally-buoyant layer) at an isopycnal, when the cooling, mixing, hydrothermally-derived fluids reach equivalent density to the ambient background.⁸ The chemical composition of hydrothermal fluids differs greatly from that of background seawater and the plume-derived fluids near an active vent can be detected using most standard properties (i.e., temperature, salinity,

chemical composition, turbidity). However, the spatial expression of the buoyant plume stem is typically no more than a few tens of square meters, making the buoyant stem difficult to localize on a survey. As emitted fluids travel further within the plume, the physically and chemically distinctive nature of the hydrothermal water mass is rapidly diluted as the plume entrains background seawater. Throughout this advective evolution of the plume, reactive (non-conservative) tracers can be consumed or transformed. Thus, despite the neutrally buoyant layer having a spatial scale extending for several square kilometers, detecting these plume fluids requires innovation in sensing and data analysis.

In this paper, we discuss the potential for water column-based hydrothermal plume discovery using standard sensing equipment (e.g., CTD, optode, transmissometer) in concert with two novel *in situ* methane instruments installed onboard an autonomous underwater vehicle (AUV) and a towed rosette. We present results from a field deployment at the northern Guaymas Basin in November 2021 and use these results to inform the planning of informative plume transects and the monitoring of real-time instrument responses. Both towed rosettes and AUVs are well-established tools for hydrothermal plume surveys. Rosettes deployed for hydrothermal plume hunting are typically used in either a vertical transect mode, or cast, performed at regularly spaced spatial waypoints along a ship transect, or a “towed” mode, in which the CTD is lowered and pulled through the water by the ship’s motion.⁹ AUVs, by virtue of being untethered from the ship, have the ability to finely control location within the water volume, and can typically operate closer to the seafloor than a towed rosette. Standard sensors mounted on either a rosette or AUV can detect different forms of hydrothermalism. High turbidity several hundred meters from the seafloor may be indicative of a neutrally-buoyant plume generated by a black smoker, whereas changes in oxidation-reduction potential

and clear waters near the seafloor may be indicative of diffuse flow. Analyzing these sensors individually and in combination can disambiguate these types of hydrothermalism and elucidate plume structure and characteristics of venting sources on the seafloor.

In 2021, our expedition aboard the R/V *Roger Revelle* (RR2107) with AUV *Sentry* and ROV *JASON*, offered a unique opportunity to examine the emission of hydrothermally derived fluids, their buoyant rise, as well as the evolution and fate of the neutrally-buoyant plume in the mid-water. Here, we present the results of a targeted lateral transect using chemical sensors mounted on AUV *Sentry* and a towed rosette, including novel *in situ* methane instruments demonstrated for the first time in the field here. Fig. 5.1 illustrates the overall design of the transect experiment. We show that methane acts as a reliable indicator of hydrothermal activity in the northern Guaymas Basin on a spatial scale of 1.5-3 km at 100-150 m altitude. Methane performed similarly to standard turbidity sensors in this trial (detection 2.2-3.3 km), more sensitively than oxidation reduction potential, and more clearly than temperature, salinity, and oxygen instruments which readily responded to physical mixing in background seawater. We additionally examine the relationships between different sensing modalities, and demonstrate how real-time cross correlative or time-series regime identification could be used to assist in survey design for future exploratory missions.

5.2 MATERIALS AND METHODS

5.2.1 SITE DESCRIPTION

Located in the central Gulf of California (Mexico), the Guaymas Basin is a mid-ocean ridge extensional spreading center system, with the unique characteristic of being heavily overlain with high amounts of organic-rich sediment. While the primary spreading center axis trends southwest to northeast, the axis of the spreading center in the more

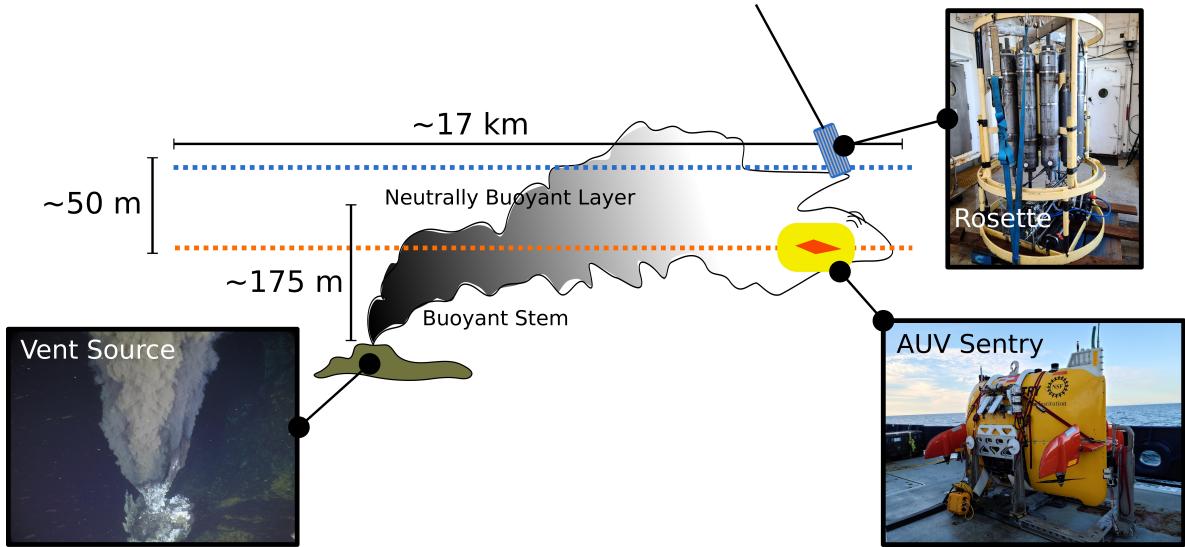

Figure 5.1: Overview of general transect design. Plumes generated by black smoking chimneys at an active hydrothermal ridge in the Northern Guaymas Basin (one example pictured here, taken with an arm mounted MISO camera by ROV *JASON* during RR2107) rise approximately 175 m in the water column and are advected and turbulently mixed with background seawater. AUV *Sentry* and a towed CTD rosette, both equipped with turbidity, oxygen, temperature, salinity, and methane probes, fly trajectories that aim to intersect the lower and upper neutrally buoyant plume layer, respectively. A comparison of the observations collected by both platforms is then used to demonstrate the efficacy of various sensors and algorithmic detection schemes.

well-studied southern end does not extend linearly northeastward, with the northern end of the axis offset to the northwest. The subseafloor eruption and emplacement of lava into the heavy sediment overburden gives rise to a unique set of hydrothermal characteristics. Among these, the geochemical composition of the emergent fluids and volatiles is highly enriched in dissolved organic compounds, carbon dioxide (CO_2), hydrogen (H_2), ammonium (NH_4^+), and methane (CH_4).¹⁰ While the southern end of the basin has been the subject of a long history of geochemical and biological examination,¹¹ hydrothermal activity was only recently documented along the northern end

¹⁰Seewald *et al.*, “Variations in the chemical and stable isotope composition of carbon and sulfur species during organic-rich sediment alteration: an experimental and theoretical study of hydrothermal activity at Guaymas Basin, Gulf of California”; Von Damm *et al.*, “Chemistry of submarine hydrothermal solutions at Guaymas Basin, Gulf of California”.

of the basin at a 600 m long ridge located at a depth of 1850 m.¹² Several tall sulfide chimneys 10-25 m in height are located along the ridge, and emit fluids highly-enriched in CO₂, H₂, CH₄ among others (Fig. 5.2). The black smoker vents associated with these chimneys consist of clusters of tens of small (<0.01 m²) orifices, emitting turbid fluids heated to over 340 °C, as observed during RR2107 by ROV *JASON*. In this work, we use the closest identified chimney to the transect trajectories at (27.407489 N, 111.389893 W) as a spatial reference point.

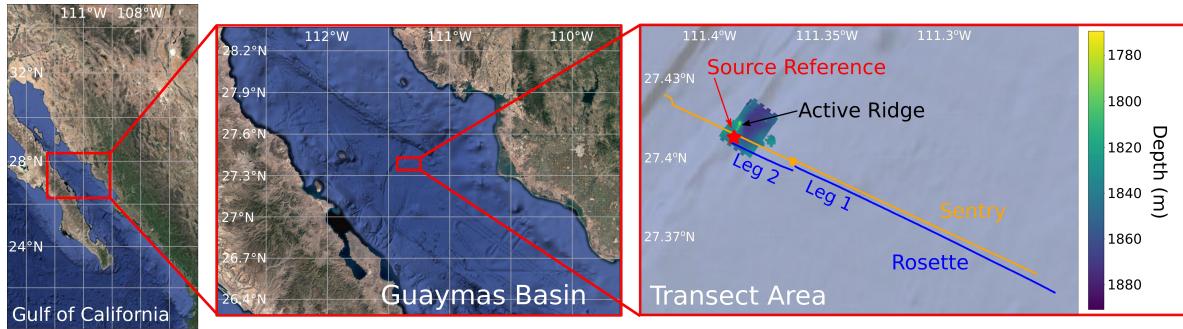

Figure 5.2: AUV *Sentry* and a towed rosette were used to perform coincident several kilometer long trajectories in the Northern Guaymas Basin. The rosette was redeployed mid-trajectory in order to empty the Niskin bottles onboard; this split the rosette trajectory into Leg 1 and Leg 2. The trajectories intersected a region of known hydrothermal activity in the northern basin; a bathymetric relief of this region is overlaid on the far right panel. The red star on the bathymetric relief marks the nearest point of identified hydrothermal activity (black smokers) relative to the trajectories (27.407489 N, 111.389893 W), and is used as a reference point in this work. Imagery is provided by the GoogleTiles API in Cartopy. The bathymetric relief is rendered using data collected by AUV *Sentry* during research cruise RR2107.

5.2.2 SAMPLING PLATFORMS AND INSTRUMENTS

During expedition RR2107, AUV *Sentry* and a towed rosette were deployed to perform a multi-kilometer transect. Two novel *in situ* methane instruments were deployed during the transect, one on *Sentry*, and the other on the towed rosette. Physical water samples collected by the Niskin bottles on the rosette were processed shipboard to measure both methane and ammonium content. To increase the total number of bottle samples that could be collected over the transect, the towed rosette was deployed and recovered twice; we will refer to the rosette transect before the first recovery as “Leg 1” and after re-deployment as “Leg 2.” AUV *Sentry* was placed in a holding pattern when the rosette was on the ship deck to ensure that spatial measurements between the platforms were temporally comparable.

AUV *Sentry*

AUV *Sentry* executes pre-set trajectories (encoded as a set of waypoints) once underway. During this transect, a starting point at (27.345152 N, 111.253108 W) and ending point at (27.460812 N, 111.527694 W) were given, and a holding pattern was programmed to be executed when the rosette was on the ship deck for sample retrieval after Leg 1. This holding pattern was centered at (27.39592 N, 111.3674 W) and was a lawnmower (back and forth) pattern of approximate dimensions 225 m x 225 m with 15 m resolution. The standard scientific instrumentation deployed on *Sentry* include an oxygen optode (Aanderaa 4330F), an optical backscatter sensor or OBS (Seapoint Turbidity Meter), an oxidation-reduction potential sensor or ORP (NOAA), a CTD (SeaBird SBE49), and 7000 m rated pressure sensor (Paroscientific 8B7000-I). The Pythia instrument (described in Sec. 5.2.2) was additionally installed onto *Sentry* for the transect.

TOWED ROSETTE

During the transect, the rosette was equipped with an ultra-short baseline (USBL) acoustic transceiver to allow the real-time position of the rosette to be tracked with respect to the ship. Scientific instruments mounted on the rosette included a transmissometer (C-Star), a 6000 m rated CTD (SeaBird SBE 911plus), twelve 10 L Niskin sampling bottles, and an oxygen optode (Aanderaa). The SAGE instrument (described in Sec. 5.2.2) was also fixed to the rosette for the transect. Default instrumentation on the rosette was communicated via the winch cable to the rosette watchstander station in the computer lab onboard the ship. Ship speed was set to $\sim 0.5 \text{ m s}^{-1}$ (~ 1 knot) to assist in controlling rosette depth and winch tension. Niskin bottles were fired according to a schedule that favored more bottles near the ridge. A scheduled stop approximately 3 km from the ridge was used to collect samples from twelve full Niskin bottles and re-deploy the rosette to take an additional twelve bottle samples from the stop to the end of the transect.

DISSOLVED METHANE ANALYSIS WITH LASER-BASED SPECTROSCOPY A Los Gatos Research (LGR) Dissolved Gas Extraction Unit (DGEU) and coupled LGR Greenhouse Gas Analyzer (GGA) were used to measure dissolved methane in seawater collected by Niskin sampling bottles fired during the transect. The DGEU uses a membrane contactor for dissolved gas extraction. Extracted gas is then pumped to the GGA which uses off-axis integrated cavity output spectroscopy for making 1 Hz, precise (<2 parts per billion) measurements of methane in the measurement range of 0-1000 ppm. Extraction of gas is imperfect by the DGEU, and so we apply an extraction efficiency correction of 2.3-3.3% (for calibration details, see Appendix A.1). Methane measurements in ppm are subsequently converted to nanomolar (nM) using coincident salinity and temperature measurements observed by the rosette CTD. Calibration of the GGA was completed

using gas standards from Mesa Gas.¹³ During the transect, nine of the twelve bottles from Leg 2 were processed using the DGEU and GGA for methane analysis.

AMMONIUM MEASUREMENT Concentrations of ammonium (NH_4^+) were determined onboard within 6 hours of collection from the Niskin bottles following the OPA method¹⁴ in a 1 cm cell using an Aquafluor Field Fluorometer (Turner Designs). Standards were prepared using Milli-Q and surface sea water, and then corrected for matrix effects following Taylor *et al.*, “[Improving the fluorometric ammonium method: matrix effects, background fluorescence, and standard additions](#)”. Analytical precision was 5 nM, with a detection limit of 1 nM. Ten of the twelve Niskin bottles were processed in this way during Leg 2 of the rosette transect.

METHANE SENSORS

Two novel sensors for *in situ* methane observation were deployed on the rosette and AUV *Sentry*. The Sensor for Aqueous Gases in the Environment (SAGE) was deployed on the rosette and a real-time cavity ringdown spectrometer called Pythia, was deployed on AUV *Sentry* (Fig. 5.3). Both instruments were in active development during this cruise, and so we report all measurements from these instruments as normalized observations (this can be interpreted as a sensor “saturation” value) in lieu of calibrated concentrations. For the purposes of the analyses herein, there is no loss of generality in the methods proposed to detect hydrothermalism using these normalized values.

SAGE SAGE is a dissolved gas sensing technology developed at the Woods Hole Oceanographic Institution (WHOI), and this expedition served as the first at-sea validation of the sensor’s operation. SAGE technology has been previously described in

¹³Michel *et al.*, “[Observations of Shallow Methane Bubble Emissions From Cascadia Margin](#)”.

¹⁴Holmes *et al.*, “[A simple and precise method for measuring ammonium in marine and freshwater ecosystems](#)”.

Figure 5.3: The SAGE and Pythia instruments mounted on the rosette and AUV *Sentry*, respectively.

Kapit & Michel, “Dissolved gas sensing using an anti-resonant hollow core optical fiber”, “Measurement of Dissolved Gases Using a Hollow Core Optical Fiber and Capillary Membrane Inlet”. Briefly, SAGE is based on infrared absorption spectroscopy performed on extracted gas from seawater via a gas permeable (and water impermeable) membrane. Once the gas enters the sensor, it fills a hollow-core optical fiber (HCF) which also guides light from a laser source tuned to measure the gas species of interest. The amount of target gas present is determined by measuring the amount of light absorption through the HCF using a photodetector. This prototype version of SAGE was configured to measure methane in the range of 0-10,000 ppm. The resolution of the sensor is <1 ppm. The response time for the deployed configuration was approximately 12 minutes, and the instrument was minimally sensitive to temperature for the scales shown in this paper, (i.e., <2% of the full scale of the observed signal). SAGE is 5.5" long with a 9" outer diameter, and the power requirement was 7 W during this field deployment.

PYTHIA Pythia is a novel deep-sea methane sensor developed utilizing real-time cavity ringdown spectroscopy (rt-CRDS) developed by WHOI¹⁵ and Ring-IR Inc.,¹⁶ and capable of operating to 4000 m depths. Pythia extracts dissolved gas from sea water using a large (113 cm²) surface area membrane. The extracted sample gas enters an optical cell where it is interrogated by a pulsed mid-infrared Quantum cascade laser (QCL). The laser light is absorbed by methane present in the cell, and the concentration of methane is determined by monitoring the pulsed ringdown signal from the cell using a mercury cadmium telluride (MCT) detector. While the response time of the sensor is slow, on the order of 35 minutes, the sensor is responsive to small (<2 ppm) changes in methane; the temperature sensitivity of Pythia has not yet been characterized. Pythia is ideally suited for long dives in environments in which changes to the methane concentration vary over long temporal and spatial scales. Details on the process for normalizing Pythia observations (which are strongly nonlinear and additionally require time correction) are provided in Appendix A.3. Pythia is 24" long with a 4.5" outer diameter, and was operated at a power range between 30-50 W during this field deployment.

5.2.3 ANALYTICAL PROCEDURE

Observations collected by sensors deployed on AUV *Sentry*, including Pythia, were merged into a single dataframe using a common 1 Hz time reference; data were linearly interpolated onto this common time reference if they did not share an exact timestamp. With the exception of the derivative of ORP signal, all data for the purposes of visualization is smoothed using a centered rolling average over 5 minute intervals. Additionally, temperature, oxygen, and salinity measurements are normalized with respect

¹⁵Michel *et al.*, “Gas sensing in the deep ocean: advancing our ability to chemically explore”.

¹⁶Harb *et al.*, “Pulsed quantum cascade laser-based CRDS substance detection: real-time detection of TNT”.

to depth (as these quantities are anticipated to be functions of depth in the weakly stratified deep waters). Depth correction is performed by fitting a linear function to the average observation collected in 20 m wide depth-bins, and computing the residuals of all data points with respect to this line (see Appendix A.4 for plots of the linear functions). Rosette data is treated in the same fashion as *Sentry* data. Down-cast and up-casts are removed from both *Sentry* and rosette data streams for all visualizations.

5.2.4 TRANSECT DESIGN AND EXECUTION

AUV *Sentry* and the rosette were deployed in the basin approximately 16 km from the northern hydrothermal ridge structure, at (27.348152 N, 111.253108 W) with a course of 295° set to intersect the southern part of the ridge (Fig. 5.2). The *Sentry* trackline was placed approximately 200-300 m north of the rosette to avoid any risk of entanglement. *Sentry* was set in altitude hold mode, targeting 120 m from the bottom (this places *Sentry* at a depth of approximately 1750-1700 m, and at the top of its altitude-hold range). Rosette depth was targeted to be approximately 1650-1600 m, controlled primarily by the speed of the ship and length of the winch cable. These depths were designed based on an estimated model of the neutrally buoyant plume layer, as described in Sec. 5.2.4. Leg 1 of the rosette trajectory was terminated at a planned stop at (27.393855 N, 111.364637 W), and Leg 2 was resumed at (27.460812 N, 111.527694 W); see Appendix A.2 for the schedule of bottle samples collected during Leg 2 presented in this manuscript. At the time of the transect, there were no known hydrothermal sites present over the sampling trajectory, save for the northern ridge. Hydrothermal vents in the southern basin were located approximately 40 km further south from the transect starting location.¹⁷

¹⁷Teske *et al.*, “The Guaymas Basin hiking guide to hydrothermal mounds, chimneys, and microbial mats: Complex seafloor expressions of subsurface hydrothermal circulation”.

MODELING TO INFORM TRANSECT DESIGN

The selection of heights for the rosette and AUV *Sentry* was informed by a simple buoyancy model of expected plume characteristics on the ridge, and known operational constraints of AUV *Sentry* (i.e., an absolute floor and ceiling of operation above the bottom). Using an adapted plume crossflow model developed by Tohidi & Kaye, “[Highly buoyant bent-over plumes in a boundary layer](#)” (see Appendix A.5 for more detailed information) with a nominal current crossflow value of 0.1 m s^{-1} , vent temperature of 340°C , and estimated background seawater stratification as per Speer & Rona, “[A model of an Atlantic and Pacific hydrothermal plume](#)”, we hypothesized that a neutrally-buoyant layer may form between 1570 m and 1750 m. We selected the depths for the rosette (1600-1650 m) and AUV *Sentry* (1700-1750 m) given this information in order to target both the upper and lower estimated neutrally buoyant layer (NBL), respectively. We targeted the NBL to increase the likelihood of intersecting plume waters during the transect over a broad, multi-kilometer scope. This is in contrast with targeting the plume buoyant stem, which though significantly easier to distinguish from background seawater, may only have an expression on the order of several square meters.

REAL-TIME DATA FEEDBACK AND WATCHSTANDING

During the transect, data from the standard rosette sensors were available in near-real time at the watchstander station in the shipboard computer lab. This allowed watchstanders to monitor the depth of the rosette and relay requests to the winch operator on deck, and display the data on live-updating visualizers. AUV *Sentry* relayed occasional data packets up to 128 bytes in length at a rate of approximately 0.01 Hz. These data packets were subsequently graphed on a computer monitor that was linked to the *Sentry* network. A total of 600 messages with information about the standard

science instruments on *Sentry*, and 583 messages with information from the Pythia instrument were transferred during the transect.

5.3 RESULTS

5.3.1 METHANE OBSERVATIONS FROM SPECTROSCOPIC INSTRUMENTS

Elevated methane was observed over a spatial scale of several kilometers, significantly rising as both AUV *Sentry* and the rosette approached the source of known hydrothermalism on the transect (Fig. 5.4). As both methane instruments used on this cruise were in active development, we report methane observations as normalized values from 0 to 1. We use a normalized value of 0.5 as a conservative threshold for classifying elevated methane measurements. Pythia, mounted on *Sentry*, reached and exceeded this threshold for elevated methane starting at approximately 3 km from the hydrothermal reference point at (27.407489 N, 111.389893 W); SAGE, flying nearly 50 m higher in the water column, reached this threshold starting 1.5 km away. For a less conservative threshold (0.3), these spatial detection points are reached 6.8 km and 2.2 km away, respectively. SAGE observed a sharp peak of methane just under 1 km from the reference source, with rapid decline of observable methane soon after. In contrast, Pythia reached a methane peak essentially at the 0 km reference point, and shows a gradual decline in methane as *Sentry* descends into a graben just north of the hydrothermal ridge; the rosette was pulled from the water at the ridge. The difference in spatial detection patterns indicated by these instruments may be a function of both the different sensor modalities/sensitivities, and the natural structure of the neutrally-buoyant layer and the relative position of the two platforms within it.

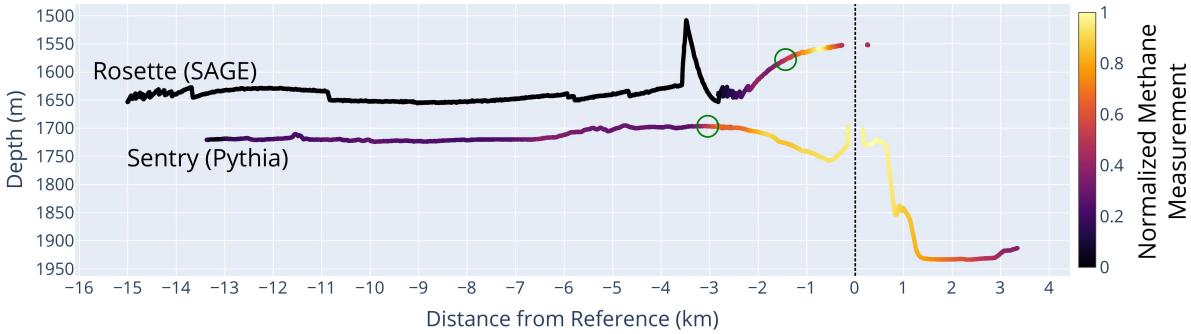

Figure 5.4: Normalized methane values observed with both SAGE (rosette) and Pythia (*Sentry*) over reference distance from (27.407489 N, 111.389893 W). The transect begins at the left of the plot and proceeds to the right. Strong methane anomalies, defined as points above a conservative threshold of 0.5 normalized values, are present starting 3 km from the reference source as observed by Pythia, and 1.5 km as observed by SAGE (open green circles).

5.3.2 METHANE AND AMMONIUM OBSERVATIONS WITH THE ROSETTE

Ammonium is a microbial energy source and reduced compound that is produced by the hydrothermal vents at Guaymas Basin. It is expected that ammonium and methane behavior in the basin will behave similarly, providing a “check” on the methane trends we observe in methane bottle samples, and recorded by SAGE. Focusing primarily on Leg 2 of the rosette transect, we observed a correspondence between methane and ammonium elevation in the approach to the hydrothermal ridge (Fig. 5.5). Methane samples processed directly from Niskin bottles as outlined in Sec. 5.2.2 show a peak methane concentration of 3000-4000 nM (this range is associated with the extremes of calibrated extraction efficiencies valid for the equipment used), approximately 0.75 km from the hydrothermal reference point. Ammonium tracks closely with methane, at 3-4 times smaller concentration, reaching a peak of approximately 1000 nM.

Normalized methane observations by SAGE generally follow the trends shown by the bottle samples, similarly showing a spatial peak at 0.75 km. However, by its nature, SAGE yields a significantly more resolved signal; a small, secondary peak is observed

by SAGE at 2 km from the reference point which is essentially missed by the bottle samples. Additionally, by virtue of operating continuously, there is no need for human interaction (unlike for processing bottle samples, which can require time-intensive *ex situ* analysis).

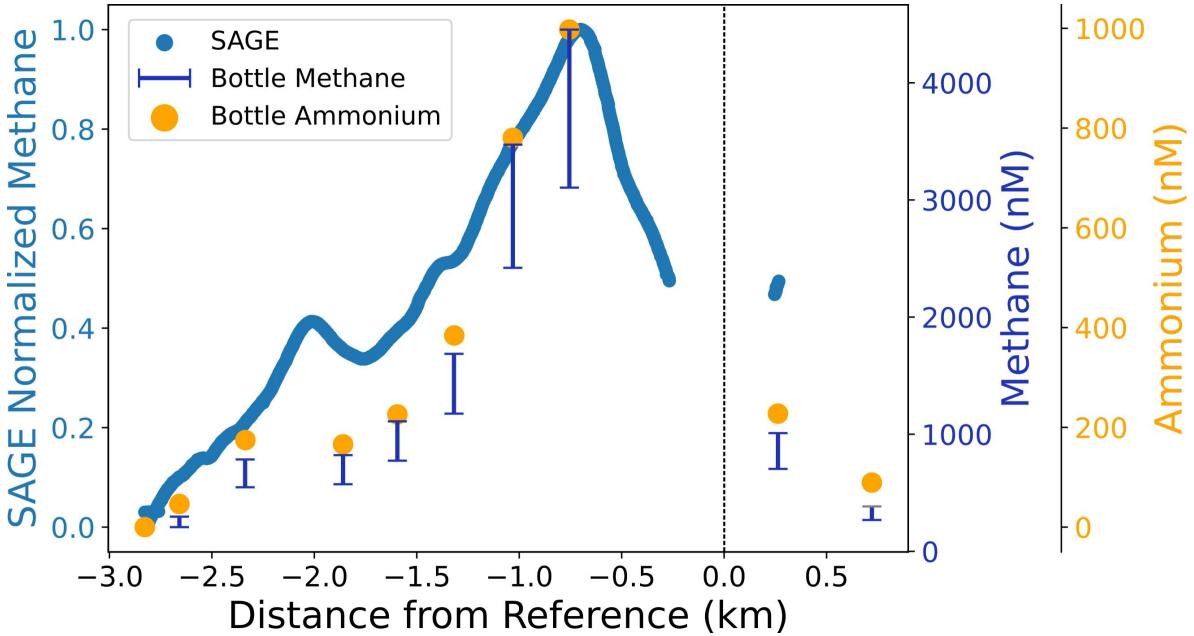

Figure 5.5: Normalized methane measurements by SAGE plotted with methane measurements taken from Niskin bottle samples (as measured by DGEU/GGA equipment) and ammonium measurements. Bottle methane measurements are reported as a range to reflect sensitivity of the measurement procedure to a calibrated extraction efficiency. All measurements trend towards a peak observation of methane and ammonium 0.75 km from the reference source. SAGE additionally observes a secondary peak approximately 2 km from the source, which is essentially missed by the bottle sample schedule.

5.3.3 TURBIDITY

Turbidity is a commonly used indicator for detecting hydrothermalism from smoking vents; particulate matter produced by smoking vents can remain suspended in the neutrally buoyant layer, acting as a non-conservative tracer for hydrothermalism.¹⁸ In

¹⁸Feely *et al.*, “Tracking the dispersal of hydrothermal plumes from the Juan de Fuca Ridge using suspended matter compositions”.

the Guaymas Basin, suspended particulates have been shown to be composed of metals like iron, aluminum, and manganese¹⁹ and are primarily mixed into bottom waters from hydrothermal activity. We report turbidity measurements as normalized values to make direct comparison between the platforms; in absolute terms, the transmissometer on the rosette reported beam attenuation values between 0-0.2 and the OBS on *Sentry* observed backscatter values between 0.08-0.14. The OBS on *Sentry* encountered an error from the beginning of the dive, potentially caused by a persistent air bubble, until approximately 4.5 km from the ridge reference point; we therefore do not report these early measurements.

We observed elevated turbidity (defined by a conservative threshold of 0.5 in the normalized data) with the transmissometer on the rosette starting approximately 2.2 km from the reference source and 3.3 km with the OBS on *Sentry* (Fig. 5.6). Even with a less conservative threshold (0.3) these detection points only slightly improve to 2.5 km and 3.4 km respectively. With *Sentry*, we observe a rapid decline in turbidity within tens of meters west of the source reference (positive distance in Fig. 5.6). This may be indicative of the direction of prevailing crossflow (southeast) in the basin, which would directionally bend a buoyant plume stem and advect the neutrally buoyant layer.

5.3.4 OXIDATION REDUCTION POTENTIAL

AUV *Sentry* carries an ORP sensor; there was no comparable sensor on the rosette. ORP sensors are commonly used in hydrothermal plume hunting, and can be a strong indicator of recently emitted hydrothermal fluids. The derivative of ORP (noted here as dORPdt) is particularly used, in which negative dORPdt values typically indicate transition from background water into hydrothermal fluid. During the transect, only

¹⁹Scholz *et al.*, “Shelf-to-basin iron shuttle in the Guaymas Basin, Gulf of California”.

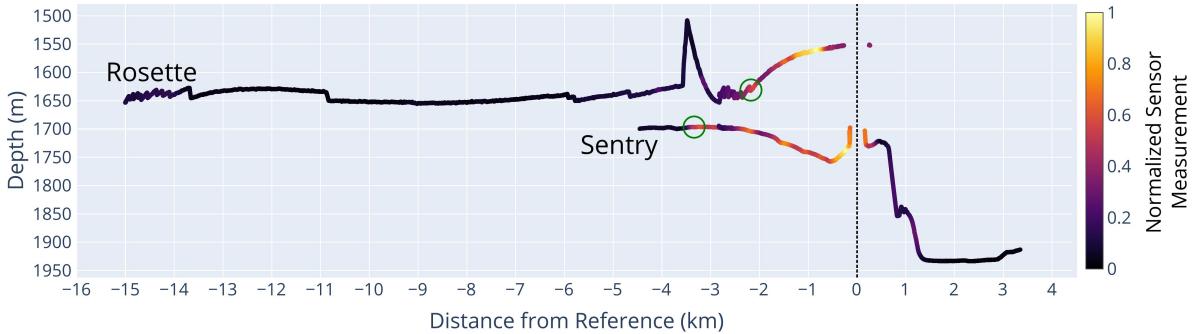

Figure 5.6: Turbidity observed as beam attenuation on the rosette transmissometer and optical backscatter on AUV *Sentry* instruments. *Sentry* encountered a sensor error until approximately 4.5 km from the ridge reference point. After this point, elevated turbidity is detectable throughout the dive, with significant elevations within 3.3 km east of the ridge reference point, dissipating within tens of meters to the west. Elevated turbidity is observed by the rosette 2.2 km from the ridge reference point to the east.

one significant dORPdt deviation was observed, within 200 m from the ridge reference point (Fig. 5.7).

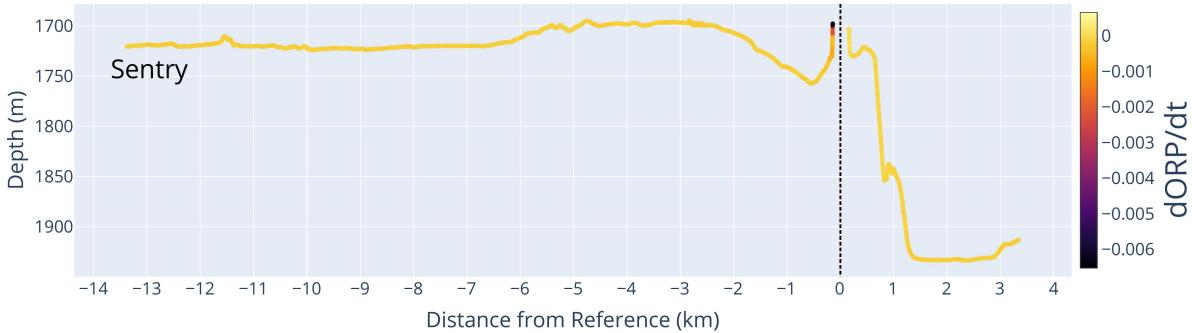

Figure 5.7: The derivative of ORP observed by data collected on AUV *Sentry*. Negative slopes are indicative of entering hydrothermal fluids. Only one region of the transect demonstrated a significant reaction to ORP, within 200 m of the reference point.

5.3.5 TEMPERATURE, SALINITY, AND OXYGEN

Temperature, salinity, and oxygen are expected to be weakly stratified in deep ocean waters, however fluids from hydrothermalism should register as anomalies when present. The magnitude of valid anomalies (i.e., anomalies that positively identify fluids impacted by hydrothermalism) can be exceedingly small; temperature at a vent can be

hundreds of degrees Celsius, but anomalies in the water column on the spatial order of only 10 m can be measured as single degrees, and within a nonbuoyant plume on the order of hundreds of meters from the source, only register a few hundredths of a degree.²⁰

We compute temperature, salinity, and oxygen anomalies according to the process described in Sec. 5.2.3 and show the results in Fig. 5.8. Salinity anomalies, although apparently coherent, are reported within the empirical sensor noise for the CTD instruments on both the rosette and *Sentry*. Temperature anomalies on the scale of hundredths of a degree are observed throughout the transect, with two key regions of high temperature anomaly, one located 6-12 km from the reference source, and the other within 3 km of the source. Both the rosette and *Sentry* observe these regions; with *Sentry* observing the first anomaly in a narrower margin between 8-11 km from the reference source. The first region of positive temperature anomaly closely corresponds with marginally fresher water; whereas the region of higher temperature anomaly near the source is not consistently matched in temperature (the rosette observes more salinity content, whereas *Sentry* observes neutral or slightly less salinity content). Oxygen is reported as nominal or slightly depleted within the regions of notable temperature and salinity anomaly.

The first region of interest, far afield from the plume reference point, appears coherent and has similar detection qualities to the near-reference region; however, given the typical expectation of temperature dissipation from hydrothermal sources, it would be surprising if this first region were connected with hydrothermalism. The shape of the warm, slightly fresher and oxygen depleted intrusion (laterally broad higher in the water column, and appearing to narrow based on the observations taken by the rosette and *Sentry* approximately 50 m offset in altitude) also does not follow expected patterns in

²⁰Yoerger *et al.*, “Autonomous and remotely operated vehicle technology for hydrothermal vent discovery, exploration, and sampling”.

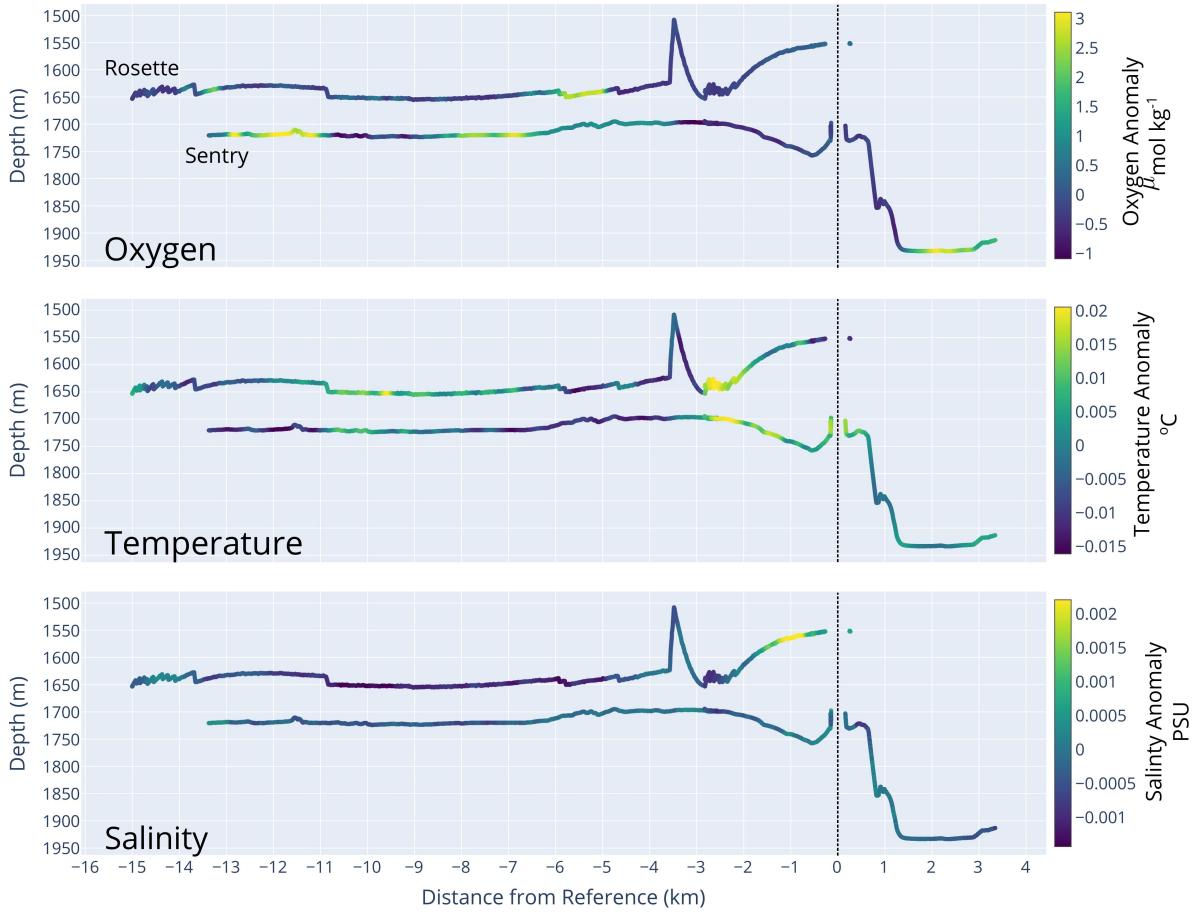

Figure 5.8: Depth-corrected oxygen, temperature, and salinity over reference distance. Two notable regions of high temperature deviation from expected temperature are observed between 6-12 km (rosette; 8-11 km by *Sentry*) and within 3 km of the reference source. The first region of temperature anomaly is closely matched with fresher salinity measurements; whereas salinity is measured as marginally higher near the reference source by the rosette CTD and nominal or lower by the *Sentry* CTD. In both regions, oxygen is nominal or slightly depleted, with regions of notably elevated oxygen at the boundary of these regions.

a neutrally buoyant plume layer. Lack of significant methane and turbidity observations in this same region, as presented in Sec. 5.3.1 and Sec. 5.3.3 respectively, additionally casts doubt on hydrothermalism as a driver for this anomaly. Water mass mixing between the bottom waters, largely sourced from Pacific Deep Waters and the Pacific Intermediate Waters²¹ may be an alternative explanation, but is out of scope for this paper to investigate.

²¹Bray, “Water mass formation in the Gulf of California”.

5.4 DISCUSSION

5.4.1 SENSOR CROSS-CORRELATIONS

Successfully detecting hydrothermalism in the deep ocean is a significant challenge, and detection may be most effective using a combination and corroboration of anomalies across multiple sensor inputs.²² Here, we examine the cross-correlation between sensors mounted on each of the platforms. Both a global and rolling Pearson correlation coefficient was computed, showing respectively overall correlation trends, and situation dependent correlation.

Fig. 5.9 shows the global correlation among sensors mounted on the rosette individually over Leg 1 and Leg 2, in addition to sensors mounted on *Sentry*. In the absence of significant geochemical features in a target environment, it is expected that no or only weak correlation will be computed globally, as individual sensor noise (which is independent) will dominate the computation; when geochemical structure is present in the environment, it is expected that weak to strong global correlation will be computed as the environment is imposing a (shared) signal across at least a subset of sensors. This is well illustrated by the cross-correlation matrices for the rosette legs, with global coefficients for Leg 1 reporting no correlation between sensors save for a slightly negative correlation between temperature and oxygen, and for Leg 2 reporting weak to strong correlations between all sensors, with notably strong positive correlation between turbidity and methane. Interestingly, in Leg 2 a negative correlation is reported between temperature and methane, and a positive correlation is measured between methane and oxygen measurements. This runs directly counter to expectations; and also counter with the relationships observed by *Sentry* which marks relationships between methane and

²²Jakuba, “Stochastic mapping for chemical plume source localization with application to autonomous hydrothermal vent discovery”.

temperature as positively correlated, and between methane and oxygen as negatively correlated.

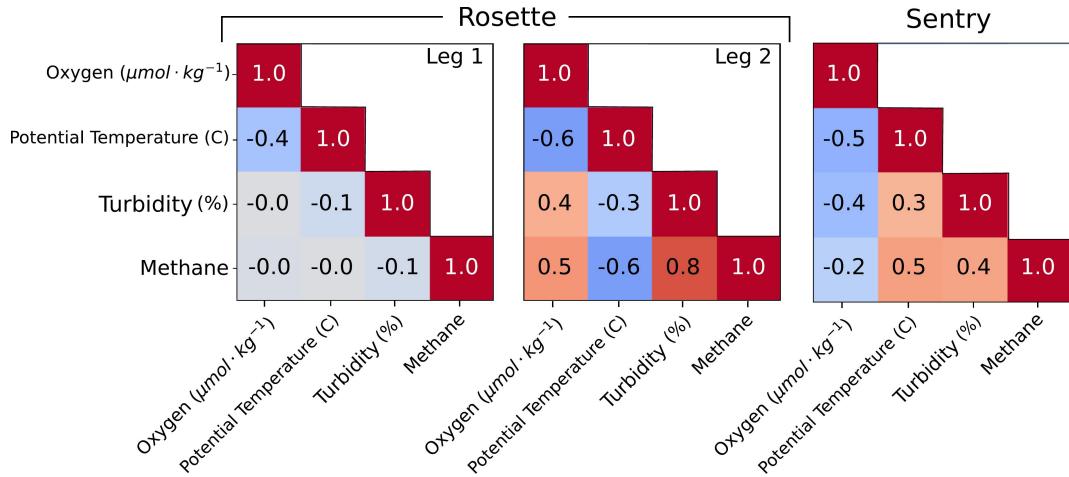

Figure 5.9: Global Pearson correlation coefficient between sensors mounted on the rosette and *Sentry*. Correlation differences between Leg 1 (far from the reference point) and Leg 2 (near the reference point) are indicative of different sensor correlation behaviors with respect to ambient seawater conditions and hydrothermal fluid interception. *Sentry* correlation coefficients reflect an expected relationship between temperature and methane (positive), methane and oxygen (negative), and turbidity and methane (positive) that may be stereotypically associated with hydrothermal fluids. In contrast, the Leg 2 rosette correlation factors do not meet this expectation, despite showing strong overall correlative structure.

The difference between correlative behaviors between the rosette legs, and also between the platforms generally, motivates a finer study of correlation. Fig. 5.10 shows a rolling correlation coefficient computed over a window of 30 minutes for the rosette. Computing local cross-correlations with respect to time, rather than distance, is mathematically more sound, and also aligns directly with how cross-correlative monitoring may be used during live exploration missions. With respect to the rosette, we observe that in Leg 1, nominal correlation is weak or non-existent between most sensors, with exception for oxygen and temperature. We can additionally see that the correlative “micro-structure” of the local window shows regions of possible interest that are greater than nominal – for instance, measurements taken between 03:00-05:00 show a coherent region of negative correlation between temperature and turbidity, and posi-

tive correlation between temperature and oxygen. Similarly, around 02:00 a region of strong positive correlation between oxygen and temperature is observed. In Leg 2, we see overall more strong, pronounced correlations between sensors, with a distinct period centered in the hour around 10:00 in which correlation between temperature and methane, temperature and turbidity, oxygen and methane, and oxygen and turbidity appear to “flip” compared to the periods of time directly before and after this period, potentially indicating a significant anomalous feature. This time period is well aligned with the spatial proximity of the rosette with the reference source.

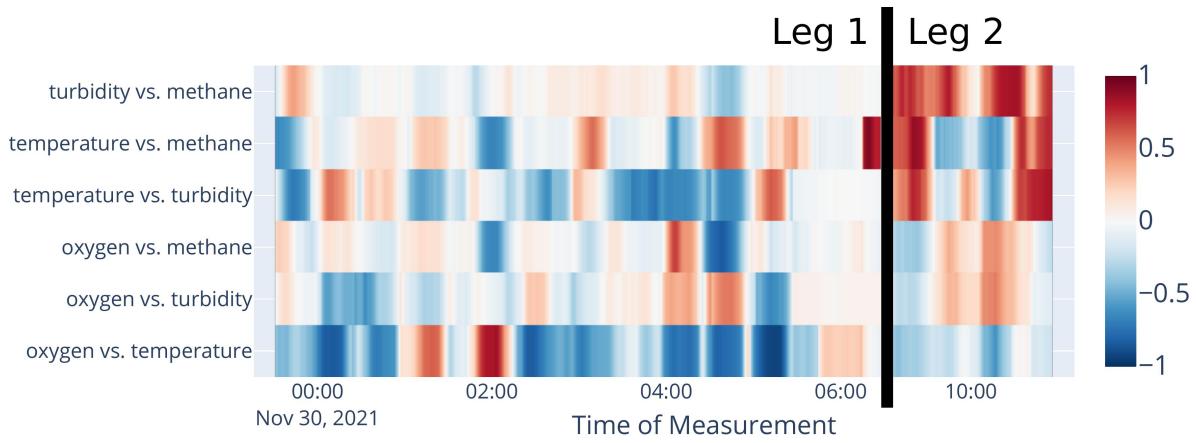

Figure 5.10: Local (rolling) Pearson correlation coefficients between sensors mounted on the rosette over 30 minute windows.

Local correlation trends during the *Sentry* transect are reported in Fig. 5.11, and show an intense relationship between oxygen and temperature throughout the dive, with most regions reporting a strong negative correlation, both with two regions showing positive correlation between 07:00-08:00 and again at 11:00. This strong relationship is also reflected in the relationships of temperature and oxygen with methane, being nearly correlative mirrors with respect to methane. During periods in which the turbidity sensor was operational, a gradual correlative “flip” and intensity increase around the 11:00 sampling time may indicate a structured water mass. This time agrees with the spatial proximity of *Sentry* with the reference source.

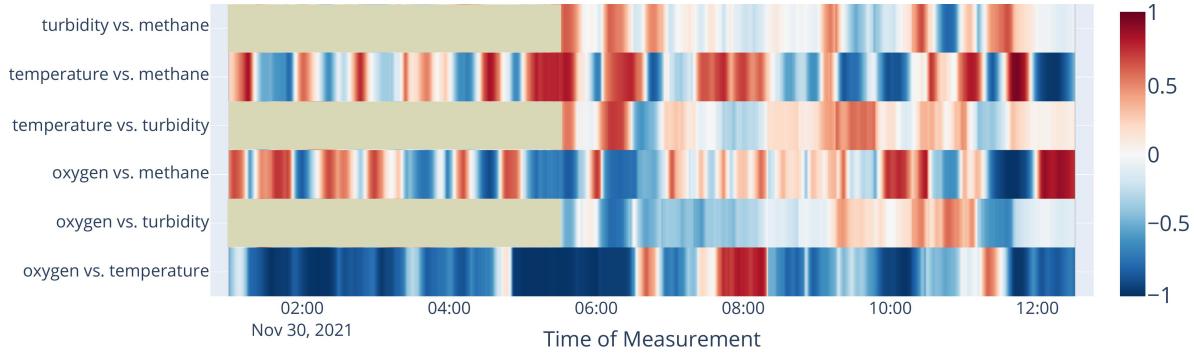

Figure 5.11: Local (rolling) Pearson correlation coefficient between sensors mounted on AUV *Sentry* over 30 minute windows.

Correlation alone is not sufficient evidence for the presence of hydrothermal fluids. For instance, some of the coherent regions of positive or negative correlation with methane any time during Leg 1, or early in the *Sentry* transect, are misleading, as the overall methane content of the water was exceedingly small or essentially background. Rolling correlations, coupled with absolute thresholds as reported in this results section, may together be useful tools for indicating transition into new water masses, their absolute properties of which could be used to more closely classify the types of water masses. This correlative study also demonstrates that correlations in expectation (e.g., temperature and methane being positively correlated in hydrothermal fluid) may be reductive assumptions of the complexities of plume evolution within a water column, supporting similar findings by, e.g., Cowen *et al.*, “[Methane in aging hydrothermal plumes](#)”. For instance, aging plume waters in the neutrally buoyant layer may long have settled to a temperature indistinguishable from background, but still be particulate and possibly gas rich. This motivates additional study of the “classes” of hydrothermal fluids and their classifying characteristics, which could in turn be used to support studies of microbial evolution and nutrient consumption in plume fluids, or sediment and particulate transport modeling.

5.4.2 HYDROTHERMALISM DETECTION VIA TIME-SERIES REGIMES

As indicated by Sec. 5.4.1, changes in correlative *structure* may be a more useful signal than absolute correlation alone. This notion can be codified as regime changes, which detect inflection points in which a series of observations collected in time may change in typical value, oscillation frequency, or pattern. Here, we compute regime changes using a 30 minute detection window using the `ruptures` Python library and a radial basis function detection kernel, and report regimes using alternating red and blue color blocks in the included figures.

In Fig. 5.12 we show uniquely identified regimes across the entire rosette transect over multiple sensors. We observe that the water-mixing anomaly that occurs early in the transect (Sec. 5.3.5) appears to be detected as regime changes in potential temperature, oxygen, and even a correspondence in lowered beam attenuation. Similarly, regime changes in turbidity and methane are early indicators of significant elevation of both of these factors as the rosette intersects with hydrothermal fluids. Interestingly, a regime change in oxygen and temperature is evident immediately following the first small peak in methane and turbidity. These peaks, in addition to these regime changes, may together be indicative of mixing plume sources from other hydrothermal vents located along the ridge (that must travel further than fluids from our reference point) or the mixing of ageing plume waters with more recently emitted fluids.

With instruments mounted on *Sentry*, in Fig. 5.13 we see clear “steps” of methane observed by Pythia each marked as a regime. Some of these steps are nearly coincident with regime changes in turbidity, temperature, and oxygen (particularly the steps at 06:30 and 09:30).

Regimes can be mathematically identified in streaming data, making this a potentially useful method to adopt for real-time hydrothermalism discovery. Coupled with absolute measurements by sensing instruments and rolling correlative structure, iden-

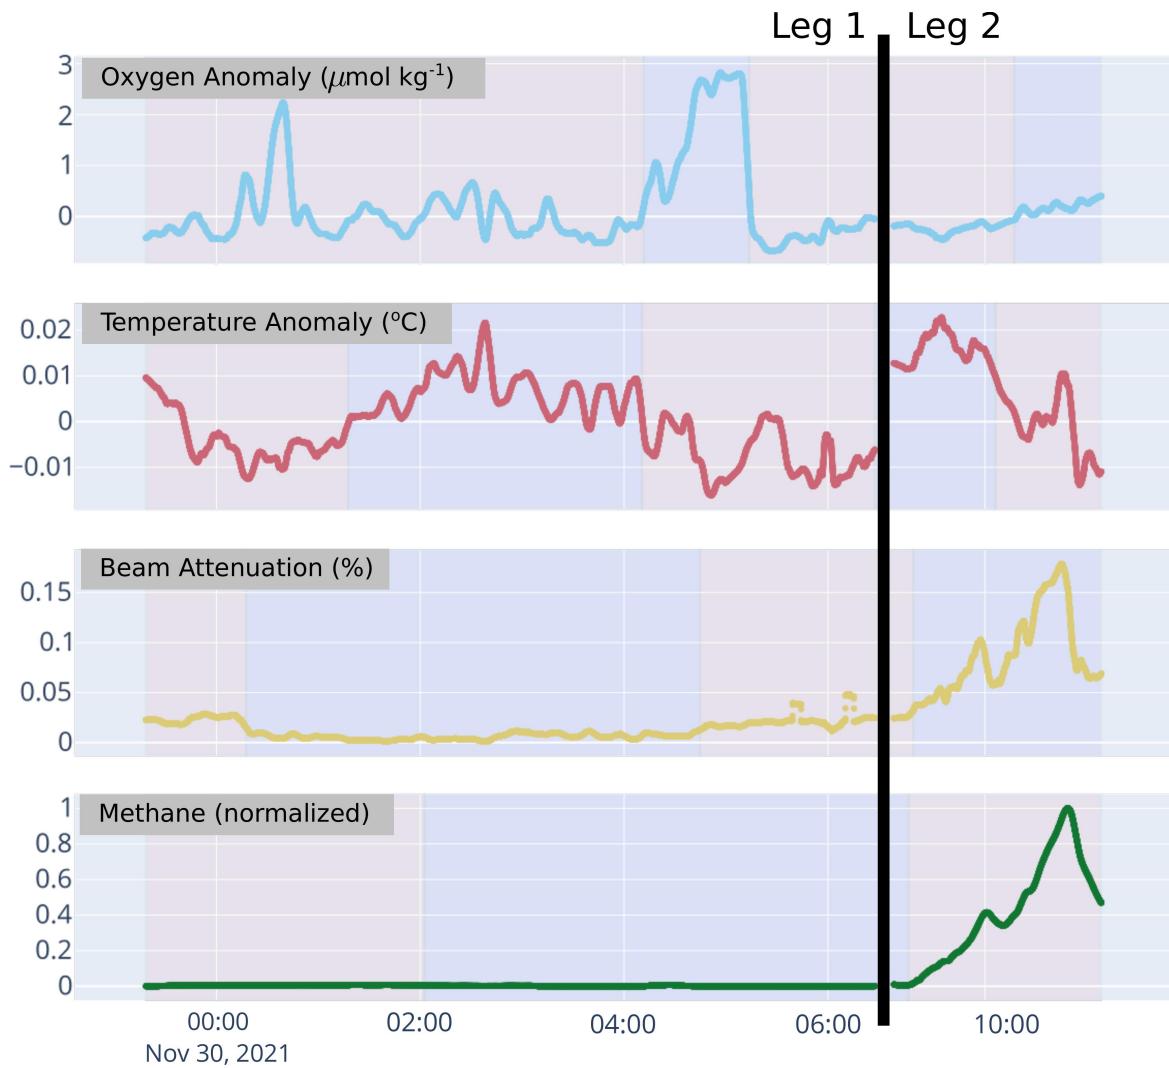

Figure 5.12: Regimes, indicated as alternating blue and red regions, detected during the rosette transect with a 30 minute detection window.

tifying water masses across multiple data streams can be done live from streaming data on the ship, or computed/estimated directly onboard an AUV computer and reported back to watchstanders remotely under data-limited transmission protocols (e.g., acoustic pings).

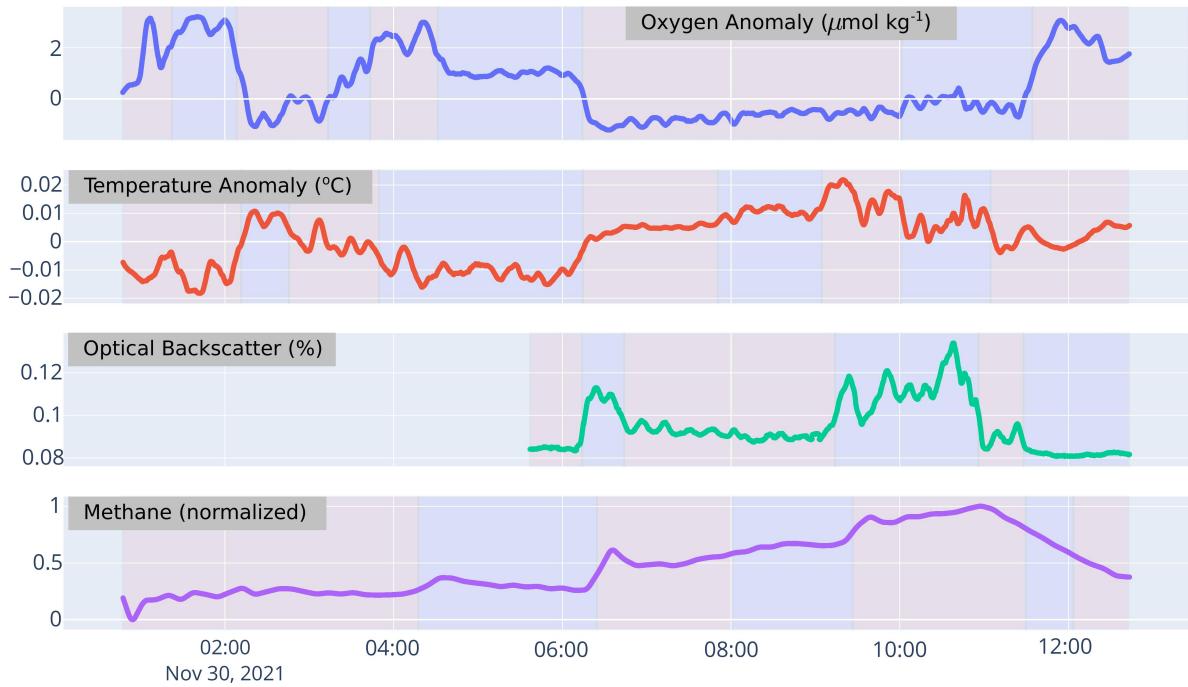

Figure 5.13: Regimes, indicated as alternating blue and red regions, detected during the AUV *Sentry* transect with a 30 minute detection window.

5.4.3 METHANE IN DEEP SEA EXPLORATION

AUV and sensor deployments during expedition RR2107 served as an initial proving ground for the SAGE and Pythia *in situ* methane instruments for deep sea exploration, and the utility of methane as a potential tracer for hydrothermalism discovery. We showed that, during this transect, both instruments observed significantly elevated methane over a span of several kilometers from a known hydrothermal source in Guaymas Basin. Methane proved to be a strong predictor for hydrothermalism that was not easily confounded by physical oceanographic events (e.g., mixing), giving it an advantage over oxygen, temperature, and salinity. Indeed, in this trial, each of the oxygen, temperature, and salinity instruments were impacted by an unknown physical feature not driven by hydrothermalism, but registered as similar scales of expected anomaly. Methane was also shown to be more expressive than ORP, which only registered a possible anomaly long after significant methane measurements were observed. Turbidity was

a similarly useful and expressive feature of hydrothermalism in this basin, with similar detection scales to methane during this transect. Notably, for less strict detection criteria (i.e., thresholds) on detection, methane significantly outperformed turbidity in terms of detection scale (positive identification up to 6.8 km away, in contrast to 3.4 km for turbidity). Turbidity and methane together make for a strong pairing for hydrothermalism discovery. While neither one alone is a "universal" proxy for hydrothermal activity—not all hydrothermalism of interest produces particulate heavy smoke (i.e., diffuse flow fields) nor do all vents produce significantly elevated methane—they are complementary indicators which can assist in deep sea exploration for anomalous water masses derived from hydrothermalism.

Collecting high resolution measurements of methane during this transect highlighted the rich structure of dissolved gasses in a neutrally buoyant plume layer over multiple kilometers, with multiple peak detections being possibly indicative of mixing novel and ageing hydrothermal fluids, the contribution of multiple sources of hydrothermalism, or complicated internal mixing causing spatiotemporal multimodal distributions of dissolved gas "pockets" throughout the layer. Bottle samples collected on the cruise verified the presence and general trend of methane observed by the instruments, but failed to resolve several features that may be of scientific interest. This motivates the use of *in situ* methane sensors for future studies of hydrothermal fluids in the water column.

5.4.4 ENABLING BETTER DECISION-MAKING FOR HYDROTHERMALISM DISCOVERY

Enabling the interpretation of real-time sensor data and adapting scientific missions accordingly are critical future skills for scientific expeditions and exploration in the deep sea. In preparation for this transect, we utilized a simple physical model to inform

the design of the trajectory and monitored progress with live data displays for both the rosette and AUV *Sentry*. While real-time data display for rosettes is now considered standard for oceanographic research, streaming capabilities of scientific data from autonomous platforms like *Sentry* is a relatively new capability. This display infrastructure enabled the science team to make note of the OBS sensor error on *Sentry* while performing the transect, caught a power and logging failure of the Pythia logger upon deployment (which, if left unresolved, would have meant an absence of all methane data associated with *Sentry* for this analysis), and allowed real-time control and decision-making about the rosette positioning and bottle firing possible. While data presented here was analyzed after the mission, several of these analyses, including rolling correlation and regime detection, could be performed from streaming observations. As a whole, the techniques in this paper present an opportunity for advancing technical infrastructure on a research vessel in order to enhance decision-making capabilities of the science party and engineering teams, both logistically to better diagnose instrument operation *in situ* and scientifically to enhance data collection.

Real-time data collection and processing could have further implications for embodied intelligence as a tool for scientific expeditions. Using models, inference methods, and streaming data, autonomous agents like AUV *Sentry* could be made capable of performing adaptive decision-making for sample collection. Hydrothermalism discovery has long been a motivating use case for intelligent autonomy at sea.²³ This transect experiment demonstrates the utility of simple models for tractable, intelligent planning, motivates the possibility of using methane as an additional, reliable data source for performing autonomous behaviors (e.g., adaptive sampling, tracking), and presents the opportunity to embed simple analytical methods for classifying hydrothermal fluids from sensor

²³Branch *et al.*, “[Demonstration of autonomous nested search for local maxima using an unmanned underwater vehicle](#)”; Jakuba, “[Stochastic mapping for chemical plume source localization with application to autonomous hydrothermal vent discovery](#)”; Wang *et al.*, “[3-Dimensional Hydrothermal Vent Localization Based on Chemical Plume Tracing](#)”; Yoerger *et al.*, “[Autonomous and remotely operated vehicle technology for hydrothermal vent discovery, exploration, and sampling](#)”.

streams. Being able to not only estimate and map the source of hydrothermal plumes, but to also chart the evolving nature of fluids in the mid-water, would enable an advancement of scientific inquiries that could be pursued with respect to hydrothermalism in the deep ocean. Such queries include the detailed structure of multiple-source plume collision, directly measuring *in situ* the 4D structure of mixing in neutrally buoyant plumes and buoyant plume stems, assessing biological activity supported by plume fluids, tracing the fate of dissolved gasses, and more. We have shown that detection of hydrothermal sources is possible on the scale of several kilometers even in this relatively small basin, and have taken some initial steps to demonstrate core data infrastructure that can improve human decision-making in hydrothermalism discovery; future work and engagement will be focused on advancing these tools to enable the next generation of scientific inquiry in the deep ocean.

7

LEARNING A STATISTICAL CLOSURE MODEL WITH FIELD DATA OF A SPATIOTEMPORAL DISTRIBUTION FOR INFORMATIVE SAMPLING

- want to put the robot in the right place at the right time
- right place is a function of spatiotemporal structure OR you'd like to extract more information from your observation model (not smooth away the structure of the field data)
- capturing spatiotemporal structure is difficult with time-averaged models which smooth away any structure that might be relevant, but it is computationally intractable to compute this online for use on a robot
- pikl formulates a fast neural compensator for time-averaged models which yields finer-grain spatiotemporal structure and the statistics of that structure which can be used in solving inverse problems and forward simulating for decision-making

A PERCEIVING

A.1 METHOD FOR METHANE MEASUREMENT FROM NISKIN BOTTLES

A Los Gatos Research (LGR) Dissolved Gas Extraction Unit (DGEU) and Greenhouse Gas Analyzer (GGA) were used to process water collected by Niskin bottle samples during the transect, and report methane concentration estimates to be compared to the *in situ* observation of normalized methane by SAGE mounted on the rosette. Measurements of methane made by the GGA are reported as the stabilized parts per million (ppm) reading provided by the instrument after consuming 3-5 L of seawater from each Niskin bottle, and are converted to nanomolar (nM) values by first computing the partial pressure of methane, and then computing molarity by estimating the solubility constant of methane using coincident measurements of salinity and temperature of the seawater at time of bottle sample collection as measured by the rosette CTD. The conversion from partial pressure to molarity is done using the `gasex` Python library, publicly hosted at <https://github.com/boom-lab/gasex-python>.

To transform GGA measurements in ppm to partial pressure, the DGEU cell pressure is used, such that $\text{ppm} \times \text{cell pressure} = \text{partial pressure}$. Additionally, gas extraction inefficiency is taken into consideration at this step; the DGEU does not perfectly extract

gas across the membrane during sampling. Extraction efficiency is used to scale the GGA measurement of methane prior to computing the partial pressure estimate by

$$\left[\frac{x_{obs} - x_{ref}}{\lambda_{eff}} + x_{ref} \right] \frac{p_{cell}}{1000} = x_{pp} \quad (\text{A.1})$$

where x_{obs} is the ppm measurement made by the GGA, x_{ref} is a methane reference value (the atmospheric concentration of methane, typically between 1.86-1.99 ppm), λ_{eff} is the extraction efficiency, p_{cell} is the cell pressure in millibar, and x_{pp} is the estimated partial pressure value, in μatm .

The extraction efficiency used in this manuscript was estimated by laboratory calibrations to be between 2.3-3.3%, consistent across different water temperatures and different test tank concentrations. In the laboratory calibration procedure, methane was bubbled in a temperature-controlled tank which was stirred before two discrete samples were taken using 60 mL syringes filled with 40 mL of water, and 20 mL of pure nitrogen gas. A DGEU, connected to the GGA, was then used to take water from the target tank, and ppm measurements by the GGA were recorded when measurements stabilized; this was done with two different DGEUs, which we label A and B. To estimate “ground truth” partial pressure of methane in the tank, the syringe samples were shaken for 2 minutes to extract the dissolved gas content, and the water drained. The samples were then processed within 24 hours on a gas chromatography instrument (Shimadzu GC-14B), run alongside a set of standards processed every 5 minutes. The measurements from the processed syringes (DGEU influent) were used as x_{pp} in Eq. A.1, the GGA observations as x_{obs} , the value 1.99 ppm used as x_{ref} , and 495 mbar as p_{cell} . The relevant data from these calibrations is available in Tab. A.1. DGEU A was the instrument used in the transect field mission as presented in this manuscript.

DGEU	Temperature (C)	Influent (μatm)	GGA Methane (ppm)	Efficiency
A	4.7	299.13	21.82	3.29%
A	4.7	512.03	6.44	0.4%

A.2 LEG 2 NISKIN BOTTLE SAMPLE SCHEDULE AND MEASUREMENTS

This manuscript presents methane and ammonium measurements collected by Niskin bottles during Leg 2 of the rosette trajectory. Table A.2 provides the schedule of Niskin bottle firing performed during Leg 2, and Table A.3 provides all data associated with those bottles collected and presented in Chapter 3 of this thesis. The range of methane nM values is provided by converting GGA methane ppm measurements as described in Sec. A.1 for the conservative range of valid DGEU extraction efficiency values.

Table A.3: Geochemical measurements associated with the schedule of bottle samples during Leg 2 of rosette trajectory. Note that methane expressed in nM is computed using coincident temperature and salinity measurements during the transect as measured by rosette CTD, and extraction inefficiency of the DGEU is compensated for as described in Sec. A.1.

A.3 NORMALIZED PYTHIA CALIBRATION

The Pythia instrument provides a significantly nonlinear output reference value when measuring methane. We correct for this nonlinearity using a reference curve computed in the laboratory before normalizing the measurements as reported in this manuscript. The reference curve was created using a temperature-fixed (3°C) tank and closed equilibration chamber, in which methane standards were bubbled until fully equilibrated before being measured by the instrument. Stable measurements by Pythia (which has a response time of approximately 35 minutes) were then recorded at different chamber concentrations. The calibration curve that results is a piece-wise linear function, shown in Fig. A.1.

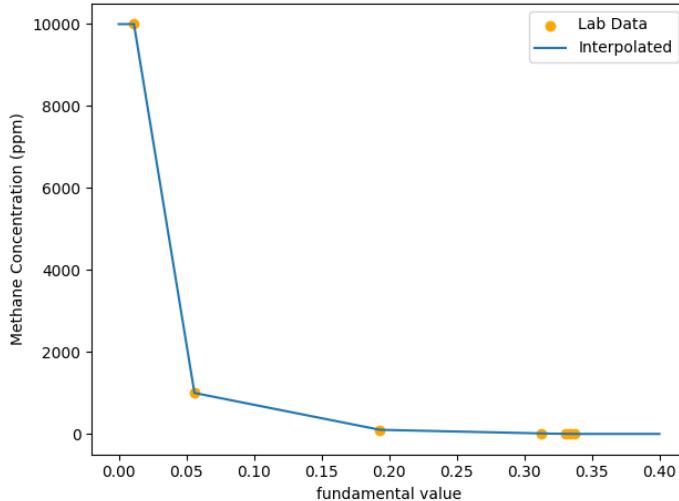

Figure A.1: Fitted calibration curve for measurements of methane observed by Pythia.

Compensation of Pythia’s time response was also performed on post-calibrated data using the methodology described in Miloshevich *et al.*, “[Development and validation of a time-lag correction for Vaisala radiosonde humidity measurements](#)” with a smoothing window of 5 minutes, and subsampling at a quarter of the time delay window. This methodology is sensitive to noise in the signal, which motivates the extreme sub-sampling that

is performed. Fig. A.2 shows the effect of smoothing, time-correction, and conversion on the direct signal recorded by Pythia before normalization.

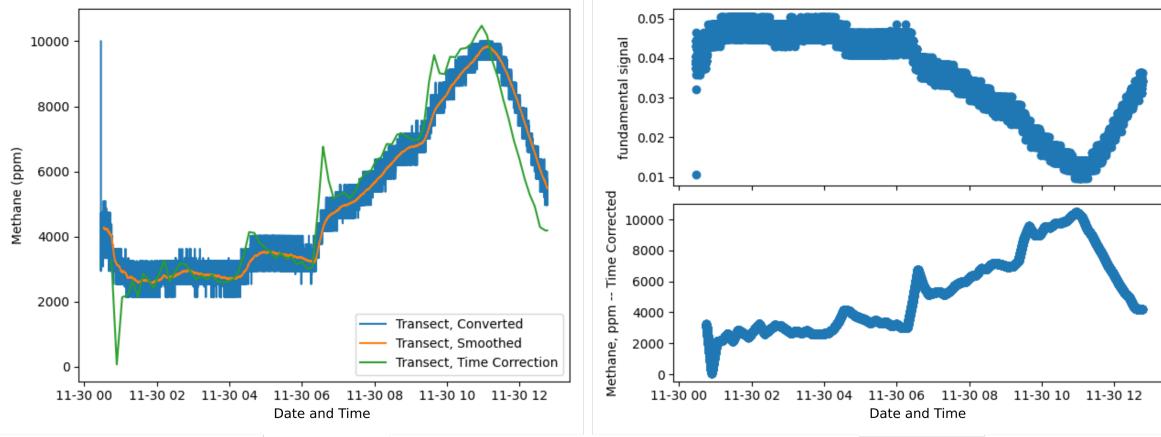

Figure A.2: Calibration curve, smoothing, and time correction applied to Pythia observations during the transect, before reported normalization in the manuscript.

A.4 DEPTH-CORRECTION

Temperature, salinity, and oxygen are expected to be weakly stratified in the deep ocean. To remove these effects from data collected by AUV Sentry and the rosette, we fit a line to the average observations collected within binned 20 m intervals of observed depth for each platform separately. Separately computing the correction for each instrument additionally controls for small discrepancies in calibration between the platforms. Fig. A.3 compares these lines with the observations collected.

A.5 DESCRIPTION OF PLUME MODEL FOR TRANSECT DESIGN

We adapted an idealized buoyant bent-plume model proposed by Tohidi & Kaye, “[Highly buoyant bent-over plumes in a boundary layer](#)” for atmospheric bent plumes in a weakly

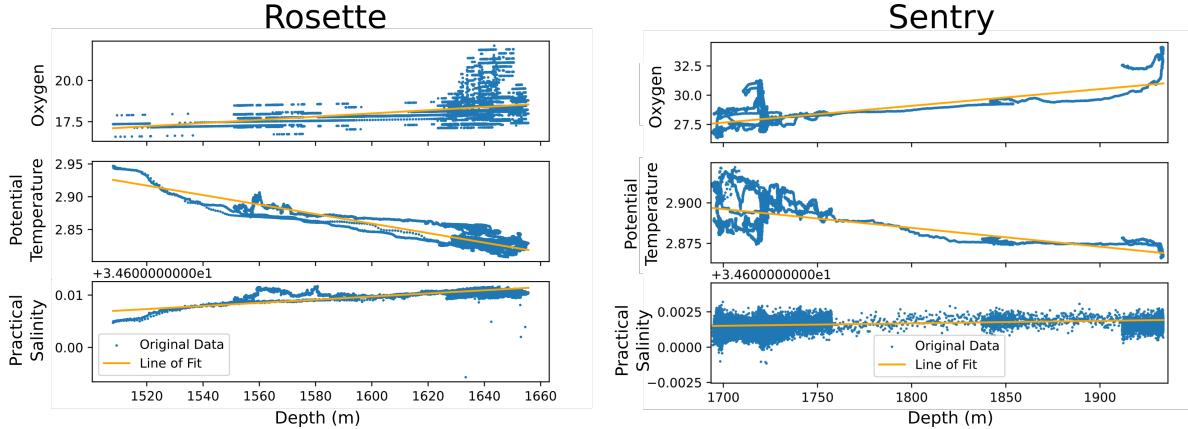

Figure A.3: Linear functions are fit to data collected for oxygen, temperature, and salinity instruments on each platform separately. A residual value is then computed for each observation.

stratified fluid in order to inform at what heights to deploy AUV Sentry and the rosette during the transect. We rewrite the system of equations provided in Tohidi & Kaye, “Highly buoyant bent-over plumes in a boundary layer” as follows:

$$E = \alpha \left| \frac{M}{Q} - u \cos(\theta) \right| + \beta |u \sin(\theta)| \quad (\text{A.2})$$

$$\frac{dQ}{ds} = QE \sqrt{\frac{2(1 + \lambda^2)}{M\lambda}} \quad (\text{A.3})$$

$$\frac{dM}{ds} = u \cos(\theta) \frac{dQ}{ds} + \frac{FQ}{M} \sin(\theta) \quad (\text{A.4})$$

$$\frac{d\theta}{ds} = \left(\frac{FQ}{M} \cos(\theta) - u \sin(\theta) \frac{dQ}{ds} \right) \frac{1}{M} \quad (\text{A.5})$$

$$\frac{dF}{ds} = -QN^2 \sin(\theta) \quad (\text{A.6})$$

$$\frac{dX}{ds} = \cos(\theta) \quad (\text{A.7})$$

$$\frac{dZ}{ds} = \sin(\theta) \quad (\text{A.8})$$

where E is a mixing entrainment coefficient which considers both vertical and horizontal mixing and is weighted by parameters α and β , u is the crossflow velocity which can be a function of depth and time, λ is a parameter which modifies the ellipse which describes the plume envelope, Q is specific volume flux, M is specific momentum flux, F is specific buoyancy flux, θ is plume centerline trajectory angle, s is the plume centerline trajectory, X is distance along a coordinate axis aligned with the plume centerline, Z is height with respect to plume source along a vertical axis, and N^2 is the Brunt-Väisälä frequency, computed with respect to the density gradient at the reference depths of the source and plume height.

The system of equations essentially yields a “snapshot” of a plume envelope at some moment in time. For time-varying crossflows, multiple snapshots can be computed for different moments in time (different crossflow orientations and magnitudes) and chained together in a common coordinate reference system in order to track a plume trajectory. For the purposes of determining which heights to deploy AUV Sentry and the rosette for the transect, we compute a prototypical envelope and use the estimated bent nonbuoyant plume height to set the transect depths/altitudes.

The initial conditions for solving this system of ordinary differential equations are set via estimates of vent characteristics including exit velocity, temperature, salinity, and area. Specifically:

$$Q_o = \lambda V_v \frac{A_v}{\pi} \quad (\text{A.9})$$

$$M_o = Q_o V_v \quad (\text{A.10})$$

$$F_o = -g10^{-4}(T_v - T_z)Q_o \quad (\text{A.11})$$

$$\theta_o = \frac{\pi}{2} \quad (\text{A.12})$$

where V_v is exit velocity at the vent orifice, A_v is the vent orifice area, T_v is the temperature at the orifice area, and T_z is the expected temperature of ambient seawater at the estimated vent depth. Note that initial buoyancy flux is primarily driven by temperature changes, as we anticipate this to be the major driver of density gradients at our measurement scale. Expected salinity gradients could be similarly considered.

Estimated vent characteristics and crossflow were selected based on empirical observations of the deep sea vents located along the northern Guaymas Basin ridge and observations of current magnitude collected by a current tiltmeter deployed by ROV Jason during several days of the research cruise. Table A.4 lists the settings for planning the transect selected for these characteristics. Background salinity and temperature profiles were computed according to standard Pacific Ocean temperature and salinity functions as described in Speer & Rona, “[A model of an Atlantic and Pacific hydrothermal plume](#)”; additionally the equation of state for computing density profile from salinity and temperature measurements was used also as defined in *ibid*. The prototypical plume is computed with a source located at 1850 m depth.

Parameter	Assignment	Description
λ	1.0	Ratio of elliptical axes of the plume envelope
V_v	0.58 m s^{-1}	Exit velocity of fluids at vent orifice
A_v	0.82 m^2	Area of vent orifice
T_v	340°C	Temperature of fluids at vent orifice
α	0.15	Longitudinal shear-driven mixing coefficient
β	0.19	Transverse shear-driven mixing coefficient
u	0.1 m s^{-1}	Magnitude of crossflow

Table A.4: Parameter, vent characteristics, and ambient crossflow setting used for transect design.

The prototypical plume envelope computed in this manner estimates a nonbuoyant plume depth between 1570-1750 m (Fig. A.4). AUV Sentry is altitude limited in order to keep a fix on the ocean floor for navigation; it is set to its maximum altitude of 120 m in order to intersect with the bottom of the estimated nonbuoyant layer; this

corresponds to a depth of approximately 1700 m throughout the basin. The rosette can be arbitrarily fixed to a height, but so as not to interfere with AUV Sentry operations and to sample a different point in the estimated nonbuoyant layer, a depth of 1650-1600 m was targeted.

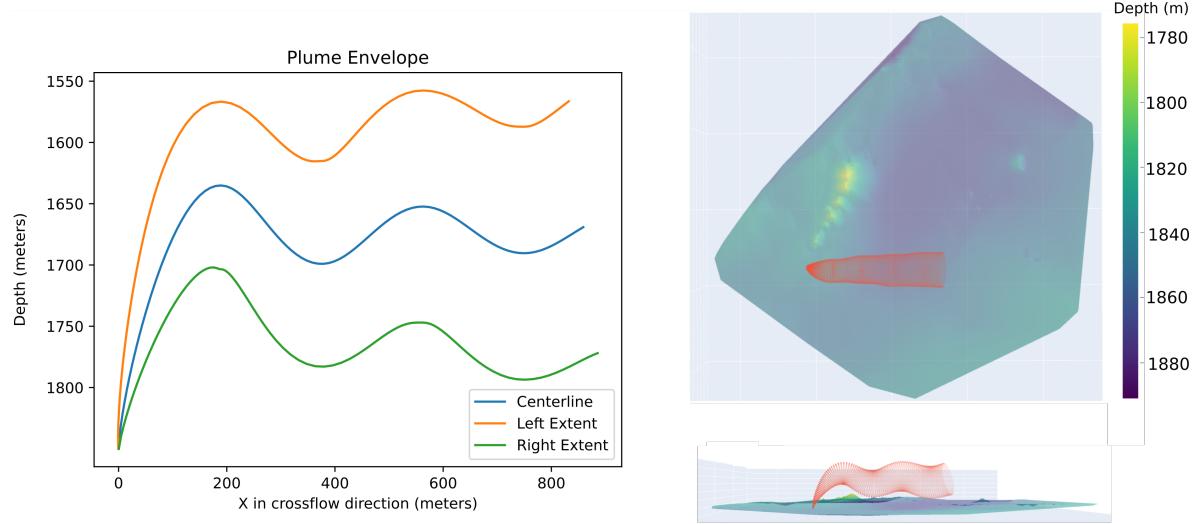

Figure A.4: A prototypical plume estimate according to the modified buoyant plume model in crossflow. The same envelope is plotted with respect to absolute depth (with a source located at 1850 m) on the left, and illustratively in the context of the hydrothermal ridge on the right.

ACRONYMS

AUV Autonomous Underwater Vehicle

POMDP Partially-observable Markov decision-process

GLOSSARY
